Biomedical Spectroscopy: Introduction

Henry H. Mantsch
National Research Council, Winnipeg, Canada

1 Introduction

Biomedical Spectroscopy, fortuitously the first section in this comprehensive encyclopedia, is one of the youngest branches of analytical chemistry. Throughout much of their history, medicine and spectroscopy have evolved quite separately, yet in the new millennium the two solitudes are closing the gap that has separated them for so long as they cross-pollinate each other increasingly. Although spectroscopy, by its very nature, has always had an interdisciplinary focus, the recent marriage between spectroscopy and medicine is only now beginning to bear fruit.

It is unfortunate that the word “chemical” has acquired such a bad reputation in the lay press and yet the same public is increasingly captivated by “natural biochemicals”. So what are natural biochemicals, and what is a natural substance? To answer this question we have to go back almost 20 billion years to when the universe arose with a cataclysmic explosion that hurled hot, energy-rich subatomic particles throughout space. Gradually, as the universe evolved, the various chemical elements were created, including those in all living organisms on earth. Hence, we humans are literally made of stardust. The unique molecules from which living organisms are constructed are called biomolecules and were selected during the course of evolution for their fitness to perform specific functions. It is therefore quite legitimate to ask what the purpose or the specific biological function of a given biomolecule in a living organism may be. When examined separately these biomolecules conform to all the physical and chemical laws that describe the behavior of inanimate matter, and yet living things possess unique properties not displayed by collections of inanimate molecules, thus presenting a distinctive challenge to the analytical chemist and to the biospectroscopist alike.

2 Overview of Contributions

The Biomedical Spectroscopy section consists of 15 articles, among which are five dedicated to optical, infrared (IR), and magnetic resonance (MR) spectroscopy. From the most ancient times, medical practitioners performed physical examinations of their patients using their eyes as optical spectrosopes. Indeed, analytical methods based on optical spectroscopy were used early in medical diagnosis, and even today many tests performed in the clinical chemistry laboratory still rely on visible spectroscopy to monitor chemical or enzymatic color reactions. Bioanalytical methods based on IR spectroscopy or on MR spectroscopy are of more recent vintage, as are several optical approaches such as optical coherence tomography or photodynamic therapy.

Biodiagnostic methods fall into two large categories: (a) biomedical spectroscopy and (b) biomedical imaging. The former is based on the interaction of selected electromagnetic waves with individual or collections of biomolecules. The resulting “molecular spectra”, represented as plots of intensity versus electromagnetic energy, provide answers to the questions “what?” (qualitative bioanalytical chemistry) and “how much?” (quantitative bioanalytical chemistry). The second category,
biomedical imaging, goes on to answer the question "where is what?", by localizing and mapping the spectroscopic information. Both biomedical spectroscopy and biomolecular imaging can be performed either ex vivo, on extracted biofluids or excised tissue, when the biomaterial is brought to the spectrometer, or in vivo, in which case the electromagnetic radiation is delivered to the target area of the patient via optical fibers, endoscopes, catheters or even through space (e.g. radio waves in MR imaging). In an ideal world, all diagnostic procedures would be noninvasive, but we live within the constraints of the real world.

The individual articles in the Biomedical Spectroscopy section are largely self-contained, each covering a particular area of expertise of the contributing author(s). A first group of contributions deals with optical spectroscopy. The term "optical spectroscopy" is not synonymous with visible spectroscopy, which at times can be confusing. Optical spectroscopy involves transitions between electronic energy levels, and thus extends beyond the violet into the ultraviolet and beyond the red into the near-IR.

Ramanujam (Fluorescence Spectroscopy In Vivo) provides a comprehensive account of optical fluorescence and absorption spectroscopy, introducing the technique, the types of chromophores and fluorophores, and the spectrometers and fluorimeters used in clinical settings. Both absorption and fluorescence spectroscopies have been explored extensively as diagnostic tools, in particular for cancer (precancer) screening in epithelial surface layers of various organ sites (cervix, bladder, gastrointestinal tract, trachial tube, and oral cavity). The contribution by Ramjiawan et al. (Fluorescence Imaging) is dedicated to optical fluorescence imaging. Fluorescence, a zero-background technique, has a much higher sensitivity and specificity than absorption spectroscopy or imaging. In particular immunofluorescence imaging, a technique based on the interaction of labeled antibodies with specific antigens, shows great diagnostic potential, even if it is not yet a common sight in hospitals. Heise (Glucose, In Vivo Assay of) tackles glucose, the Holy Grail of all analytes assessed in biological fluids. It is the dream of many diabetics, and of their attending physicians, to do away with the daily finger pricking and to depend on a simple, noninvasive optical wand for determining their blood glucose levels. As the reader will find out, great progress has been made towards this goal, but we are not quite there yet. Fercher (Optical Coherence Tomography) provides an up-to-date synopsis of the novel field of optical coherence spectroscopy and tomography, addressing a number of applications in medicine that range from ex vivo biopsy studies in dermatology, urology, and gynecology to in vivo imaging in ophthalmology, dentistry, and gastroenterology. Another type of optical spectroscopy suitable for medical applications, photodynamic therapy, is reviewed by Röder (Photodynamic Therapy). Photodynamic therapy, known as PDT to its practitioners, uses photosensitizers that are nontoxic in the dark but become toxic after photoactivation by light. The evolution of photodynamic treatment over three generations of photosensitizers is illustrated by a number of clinical applications with particular emphasis on skin diseases and cancer.

A second group of contributions deals with IR spectroscopy, a more recent tool in medical research and practice. Both IR spectroscopy and the complementary technique of Raman spectroscopy, derive information from the vibrations of chemical bonds in the biomolecules of interest and are therefore referred to as vibrational spectroscopies. Jackson and Mantsch (Infrared Spectroscopy, Ex Vivo Tissue Analysis by) introduce the reader to the basics of ex vivo tissue analysis by mid-IR spectroscopy, focusing on two facets of such an analysis. First, there is an experimental aspect related to potential pitfalls with spectroscopic measurements on samples as complex as human tissue. The second aspect concerns the interpretation of spectra, meaning the proper translation of spectroscopic information into diagnostic, medically relevant information using such tools as chemometrics and nonsubjective multivariate statistical classification methods. Every type of human tissue, although structurally highly complex, has a unique vibrational pattern (fingerprint) in the mid-IR region, which is different in healthy and in diseased tissue. This has led to the creation of a new field, IR histopathology. In vivo tissue analysis by IR spectroscopy is addressed by Sowa et al. (Near-infrared Spectroscopy, In Vivo Tissue Analysis by). Compared to both visible light and mid-IR radiation, near-IR light can traverse a greater distance into tissue, therefore the spectral range of near-IR is ideally suited for in vivo tissue spectroscopy and imaging. The penetration depth of near-IR light is of the order of several centimeters, whereas only the top \(10-20\,\mu\text{m}\) of tissue can be explored by mid-IR light. The clinically relevant tissue chromophores oxy- and deoxyhemoglobin, oxy- and deoxymyoglobin, oxidized and reduced cytochrome \(c\), as well as water, provide vital information related to oxygen delivery, storage, utilization and tissue hydration/dehydration. The article by Shaw and Mantsch (Infrared Spectroscopy in Clinical and Diagnostic Analysis) offers an overview of the clinical analyses that have been carried out by IR spectroscopic methods on such common biological fluids as serum, whole blood and urine, as well as on less-common body fluids such as amniotic fluid, synovial fluid, cerebrospinal fluid, and saliva. The term "IR clinical chemistry" was coined as an analytical technique that does not require chemical or biochemical reagents for the quantitative determination of analytes; instead, the analysis relies on chemometric algorithms. A
digression into the realm of microbiology, utilizing mid-IR spectroscopy as the investigative tool, is recounted by Naumann (Infrared Spectroscopy in Microbiology). This methodology offers an alternative analytical tool for the detection, enumeration, classification and identification of pathogenic bacteria in a clinical setting. Finally, Ozaki and Noda (Two-dimensional Vibrational Correlation Spectroscopy in Biomedical Sciences) introduce the reader to a new modality for extracting additional information from IR spectra. Two-dimensional correlation spectroscopy already has revolutionized MR spectroscopy and is expected to benefit IR biomedical spectroscopy as well.

A third group of contributions explores nuclear magnetic resonance (NMR) in medicine. There is now a tendency to drop the “N” in NMR, because the word “nuclear” is unpopular. Even though optical and IR spectroscopy have been around much longer, MR spectroscopy enjoys remarkable success today. Winter and Bansal (Magnetic Resonance, General Medical) provide an authoritative overview of multinuclear NMR in medicine. As MR spectroscopy involves the absorption of certain radiofrequencies by individual nuclei in a magnetic field, it must be performed in a magnet. The higher the magnetic field, the greater the detection sensitivity, a fact which has fuelled the race for ever higher-field magnets. Smith and Blandford (Magnetic Resonance in Medicine, High Resolution Ex Vivo) introduce the reader to the intricacies of ex vivo high-resolution MR spectroscopy in medicine. The applications they highlight range from the study of inborn errors of metabolism to the diagnosis of neurological disorders and many types of cancer. The last three contributions describe various MR imaging modalities. Richards (Multinuclear Magnetic Resonance Spectroscopic Imaging) discusses MR spectroscopic imaging, a procedure for generating spatially resolved maps and images of selected biomolecules in tissue (ex vivo), or in the body (in vivo). This molecular-level imaging, also known as chemical shift imaging, is similar to chemical group imaging by IR spectroscopy. Both imaging modalities allow the noninvasive mapping of chemicals in the body, although IR imaging is limited to external body parts such as skin, whereas the whole body is accessible to MR imaging. Richter (Magnetic Resonance Imaging, Functional) familiarizes the reader with functional magnetic resonance imaging (fMRI), perhaps the most powerful imaging technique available today. The stellar performance of fMRI in the field of neuroscience has filled in many blanks on the human brain map, and fMRI is now a premier method for the study of brain function. Finally, Yuan (Magnetic Resonance Angiography) exploits the emerging use of MR in angiography, an area until recently reserved for X-ray radiologists. The name “angiography” applies to any imaging modality that can visualize blood vessels and blood flow. Potential clinical applications are discussed, the challenge being coronary MR angiography because the three-dimensional structure of the coronary tree changes shape during each heart contraction. A concern sometimes voiced with in vivo imaging is the potentially harmful electromagnetic radiation. Although this may apply to X-ray imaging, molecular spectroscopic imaging uses low-energy electromagnetic fields and very few adverse effects have been recorded.

3 APOLOGIA AND OUTLOOK

While I want to thank all the contributing authors for their effort and dedication, as editor of the Biomedical Spectroscopy section I also apologize to my colleagues in the biospectroscopic community whose work could not be included. I had to be selective and no doubt this selectivity reflects my own bias and preoccupations with certain aspects of the exploding field of biomedical spectroscopy. As to the future of biomedical spectroscopy, I am optimistic that in the process of growing and maturing it will embrace other traditional areas of analytical chemistry. When pressed to be more specific, I would like to refer the reader to a statement by Alan Kay, one of the founders of Silicon Valley in California, “the best way to predict the future is to invent it”. So, good luck and “happy hunting grounds” to future generations of bioanalytical chemists.

A number of fluorescence imaging techniques show diagnostic promise. Imaging endogenous fluorescence has been proposed as a method for cancer diagnosis. Unfortunately, tissue autofluorescence is relatively weak and poor contrast between malignant and normal tissue is seen. Contrast may be enhanced with the addition of fluorescent materials that are selectively accumulated by malignant cells, such as fluorescein or porphyrin derivatives. The limited penetration of light at the emission maxima of these materials restricts the use of fluorescence techniques utilizing these chromophores to superficial phenomena. However, many potential applications still exist. For example, monitoring fluorescence during surgery may allow resection margins to be clearly delineated.

Other exogenous chromophores that may have may have diagnostic utility include indocyanine green (ICG). Techniques based upon visualization of the distribution of ICG fluorescence (i.e. choroidal angiography) are already prominent in ophthalmology. ICG fluorescence imaging may also find a useful niche in monitoring of burns and transplant tissue. In addition, monitoring of vascular parameters during cardiac surgery presents exciting opportunities. For example, low oxygen levels (e.g. during bypass surgery) in the heart can result in alterations in microvascular permeability. As ICG is largely bound to serum albumin, it should not be seen in extravascular spaces in normal hearts. However, increased permeability will allow albumin to diffuse into the extravascular spaces, and diffuse fluorescence across the surface of the heart will be seen. In principle, the infusion of polymers (e.g. dextrans) of various molecular weights labeled with dyes that fluoresce at various wavelengths will allow the assessment of the porosity of capillary beds in such systems.

Immunofluorescence techniques have the potential to provide unmatched sensitivity and specificity. The unique nature of antibody–antigen interactions ensures specific delivery of the fluorophore to the site of interest. The specific interaction of labeled antibodies with antigens means that the fluorophore persists in the body for a prolonged period of time (days). Following a single injection of labeled antibody, repeated measurements on the same site over the course of hours or days allow kinetic information to be readily obtained. In principle, this means that the effect of therapeutic intervention, i.e. radiation therapy, chemotherapy, etc., can be monitored.

1 INTRODUCTION

Owing to their high sensitivity, fluorescence techniques have found a valuable place in biology. The sensitivity of fluorescence methods is due in large part to the fact that they are “zero background” techniques. In other words, in the absence of the chromophore of interest, no signal (other than random noise) can be detected. Any signal that is detected must therefore arise from the chromophore of interest.

Fluorescence methods with potential for use in medicine utilize both intrinsic and extrinsic chromophores. The number of intrinsic chromophores (i.e. chromophores that occur naturally in tissues) is limited; the most important are listed in Table 1. A number of literature reports suggest that tissue nicotinamide adenine dinucleotide (reduced form) (NADH) fluorescence may prove useful in the detection of malignancies, the rationale being that changes in the metabolic status of malignantly transformed cells are reflected in changes in fluorescence signals arising from NADH. Finally, intrinsic fluorescence is typically low in most tissues and applications to date are limited. Furthermore, extrinsic chromophores of use (i.e. chromophores which are added to samples in some
manner) is obviously much wider, and fluorescent chromophores are available covering a wide spectral range [from the visible to the near-infrared (NIR)]. Typically, extrinsic chromophores are introduced into samples either as free agents or attached to carrier materials such as antibodies to specific materials present in the sample.

Detection of fluorescent materials in samples may be achieved using either spectroscopic or imaging technologies. Spectroscopic techniques may be used to analyze small regions of tissue and provide information relating to the average concentration of fluorescent materials within the sample. Fluorescence spectroscopy may be performed in vitro, e.g. using homogenized tissues, or in vivo, e.g. with the use of fiber-optic bundles. The advantage to the spectroscopic approach is that fluorescence across the entire spectral range of interest is acquired, allowing information on multiple chromophores to be obtained with one measurement. However, the obvious disadvantage to this approach is that only a small volume of tissue can be analyzed, and the resulting signal is an average signal from that tissue volume. Spatial information is not obtained.

Spatial information may be obtained by fluorescence imaging, in which the distribution of fluorescence intensity is measured as a function of position within the sample. Fluorescence imaging is typically achieved using imaging arrays such as charge-coupled device (CCD) cameras equipped with appropriate filters. While spatial information may be obtained in this manner, fluorescence imaging has typically been performed at a single frequency. Thus, spectral information is lost. Multiple imaging frequencies (to detect multiple chromophores) require changing between multiple filters, a tedious procedure. The development of the liquid-crystal tunable filter (LCTF) has removed this limitation. The transmission characteristics of LCTFs may be varied under computer control, allowing the user to vary the imaging wavelength without changing filters. With such filters, fluorescence spectroscopic imaging becomes feasible.

2 CHROMOPHORES

2.1 Endogenous Chromophores

Although a number of endogenous fluorescent chromophores exist in the body (see Table 1), their use in in vivo fluorescence studies can be problematic. The most common problems are as follows:

1. The low level of fluorescence typically seen in tissues.
2. Overlap of excitation and emission wavelengths for absorption. Many endogenous chromophores may be excited at similar wavelengths. For example, collagen fluorescence may be stimulated by illumination at 340 nm, very close to the excitation wavelength of NADH (350 nm). Overlap of excitation and emission wavelengths can be even more problematic. For instance, whereas tryptophan and NADH fluorescence is characterized by well separated excitation wavelengths (275 and 350 nm, respectively), the emission maximum for tryptophan fluorescence is seen at 350 nm. Hence, tryptophan fluorescence at 350 nm may be masked owing to absorption of the emitted radiation by NADH.

3. Ultraviolet (UV) or visible excitation and emission maxima. As discussed above, chromophores that exhibit excitation and emission maxima in the UV or visible spectral regions limit studies to the characterization of superficial structures, owing to limited penetration of light through tissues at these wavelengths. In addition, illumination of tissues with UV light is obviously undesirable.

Despite these limitations, imaging fluorescence arising from endogenous chromophores has been demonstrated to have clinical potential, particularly in the diagnosis of malignancies. For example, it has been demonstrated that malignant tissue shows enhanced accumulation of endogenous porphyrins, which exhibit fluorescence in the red part of the visible spectrum. It has therefore been suggested that changes in fluorescence arising from endogenous porphyrins may be useful in tumor detection. Differences in NADH fluorescence are also apparent between normal and malignant cells and tissues. NADH exhibits relatively strong fluorescence at 350 nm, whereas its oxidized counterpart, NAD\(^+\), exhibits only weak fluorescence. The ratio of NADH to NAD\(^+\) is decreased in malignant tissues, thus leading to a reduced fluorescence signal in malignant tissues. It should be stressed that factors that result in metabolic disturbances may also potentially affect NADH/NAD\(^+\) ratios and produce altered tissue fluorescence signatures. The specificity of NADH fluorescence methods for malignancies is at present unclear.
2.2 Exogenous Chromophores

Exogenous chromophores are those introduced into samples by some mechanism either to allow the detection of specific materials (e.g. when attached to antibodies), to probe environmental parameter (e.g. pH) or to provide contrast (e.g. angiography). As discussed above, the number of potential exogenous fluorescent chromophores is large, allowing greater flexibility in the choice of the spectral range to be employed for excitation and emission monitoring. In fact, in many instances chromophores can be chemically tailored to meet excitation and emission criteria.

The chromophore of choice depends upon a number of factors, including the nature of the experiment, excitation and emission wavelengths and chemical structure. Chemical structure is important if the fluorophore is to be attached to a carrier material: the fluorophore must contain a reactive group or be capable of derivatization or produce an active group which will allow chemical linkage to the carrier material. In many respects, the limitations in chromophore selection imposed by the nature of the experiment and excitation and emission wavelengths are more severe. The applications of fluorescent dyes that show excitation and emission wavelength maxima in the UV or visible regions of the spectrum are restricted owing to the limited penetration of UV and visible light into tissues. Thus only fluorescence signals from superficial chromophores can be recorded in these spectral regions. Dyes which fluoresce in the far-red or NIR regions have greater potential diagnostic use, owing to the enhanced penetration of light through tissues in these spectral regions.

2.2.1 Ultraviolet/Visible Fluorophores: Porphyrin Derivatives

Any fluorescent material that is selectively accumulated by tumor cells can in principle be used as a diagnostic marker. In this respect, many therapeutic agents have potential as diagnostic agents. Porphyrin derivatives used in photodynamic therapy are particularly well suited in this respect.\(^6\,10\,15\) Already used as therapeutic agents (with toxicity data, etc., available) these agents are selectively accumulated by malignant cells and exhibit fluorescence. Illumination with light at around 400 nm allows a fluorescence signal to be imaged in tissues and cells at 600–650 nm, depending upon the nature of the porphyrin derivative. The utility of this approach has been demonstrated by imaging the fluorescence arising from a hematoporphyrin derivative accumulated in colon adenocarcinoma cells implanted in the leg of a rat. Illumination at 337 nm 24 h following administration of a low dose of the porphyrins resulted in detectable fluorescence and visualization of the tumor.

Accumulation of porphyrins, including hematoporphyrin derivative and protoporphyrin IX, have been used to diagnose a number of forms of cancer in humans. In vivo fluorescence imaging of skin showed higher fluorescence in basal cell carcinomas lesions than the surrounding normal tissue. Clear demarcation of lesion borders was seen in images. Malignant tumors of the breast, head and neck region and urinary bladder have been visualized using a fluorescence imaging system using 100-ns long optical pulses at 390 nm delivered via an endoscope system which was also coupled to the imaging system. Tumor detection was achieved based on differential fluorescence between normal and malignant tissue, related to the selective uptake of tumor-marking agents such as hematoporphyrin derivative and levulinic acid, and natural chromophore differences between various tissues. A clear demarcation from normal surrounding tissue was found in measurements of superficial bladder carcinoma and in vitro investigations of resected breast cancer.\(^16\)

While the use of porphyrins as chromophores in fluorescence imaging is appealing, it is not without drawbacks.\(^6\,7\,10\,14\) The most important drawbacks are the time required to achieve significant differential accumulation of the porphyrin in malignant tissue and potential side effects such as photosensitization.

2.2.2 Visible Fluorophores: Fluorescein

In contrast to porphyrin derivatives, toxic side effects associated with fluorescein use are minimal. Fluorescein has been used for many years in studies of the vascular beds within the eye. Illumination of the retina with blue light produces green fluorescence in the vessels of the eye following injection of a bolus of fluorescein. Acquisition of images (typically with the use of photographic film) of the distribution of fluorescence produces angiograms, images of the vessels within the eye. While fluorescein angiography is slowly being superseded by ICG angiography, other applications of fluorescein fluorescence are being pursued.

Malignant tissues show an enhanced accumulation of fluorescein compared with normal tissues. At neutral pH fluorescein exists as a mixture of charged and uncharged species. Accumulation of fluorescein by cells results from passive diffusion of the neutral form of the dye across the cell membrane. In malignant tissues, the extracellular pH is often lower than that seen in normal tissue. This lower pH shifts the dissociation curve of fluorescein, resulting in a higher concentration of the neutral form of the dye in the extracellular fluid. This in turn results in an increased passive diffusion of the dye across the cell membrane. As tumor cells are generally able to maintain a neutral intracellular pH, the equilibrium within the cell is shifted.
in favor of dissociation, reducing the concentration of the neutral form of the dye and reducing outward diffusion. The dye therefore accumulates within malignant cells.\(^{(17)}\)

Preferential uptake of fluorescein by malignant tissues has been known for more than 50 years. However, the dye exhibits green fluorescence when excited with blue light. In other words, the excitation and emission maxima are both in the visible portion of the spectrum. Penetration of visible light through tissues is poor and fluorescein spectroscopy and imaging are limited to accessible surfaces. Fluorescein imaging is therefore most useful if endoscopic techniques are used to study organs such as the lungs or the gastrointestinal tract. Endoscopic detection of fluorescein fluorescence has been demonstrated for gastric cancer. Even more promising is the finding that dysplasia could be detected based upon fluorescein fluorescence in 22 of 23 specimens of cheek pouch from carcinogen-treated Syrian hamsters.\(^{(9)}\)

Of course it should be noted that conditions other than malignancies might induce a fall in extracellular pH, e.g. inflammatory conditions. If such conditions are also associated with maintenance of intracellular pH, i.e. the formation of a pH gradient across the cell, then they may show fluorescein accumulation and enhanced fluorescence may result. The specificity for fluorescein for malignant tissues has yet to be determined.

### 2.2.3 Near-infrared Fluorophores: Indocyanine Green

If information from deeper, non-surface structures is required, fluorophores that exhibit excitation and emission maxima in the far-red or NIR spectral regions, in which tissues are relatively transparent to light, are required.

The most widely used NIR fluorescent dye is ICG (also known as Cardio-Green or Fox Green). ICG exhibits absorption and emission maxima at 780 and 810 nm, respectively, wavelengths at which light can readily traverse several millimeters of tissues. Originally used to monitor cardiac and hepatic function (based upon the transit time of a bolus of the fluorescent dye through the circulatory system), ICG has recently become more widely utilized as a contrast agent in studies of the vasculature.\(^{(18–21)}\)

The most common application of ICG fluorescence in vascular studies is without doubt in choroidal angiography, i.e. imaging the choroidal vessels of the eye, vessels that provide 70% of the nutrient flow to the retina. A discussion of this active field of clinical use is beyond the scope of this article and the interested reader is referred to a number of papers on this subject.\(^{(18,22–24)}\) It is sufficient to say here that by coupling a CCD camera to the fundus camera normally used to view the retina in a clinical setting, fluorescence images of the choroid vasculature can be obtained. By studying the time course of fluorescence changes in images, hemodynamic information can be obtained. Static images and hemodynamic information can be used to evaluate vision-related problems such as age-related macular degeneration.\(^{(18,25)}\)

Monitoring tissue vascularity is important in many other clinical settings, and ICG fluorescence imaging may play an important role in these areas. One obvious application of ICG fluorescence imaging is monitoring vascularization of tumors. Typically tumors have high metabolic rates, and so have requirements for high rates of blood flow. As the tumor develops, this high blood flow requirement is met by neovascularization, that is, the formation of new blood vessels. Thus many tumors are extremely well vascularized. Imaging the distribution of blood vessels within tumors is therefore of potential diagnostic utility. This technique has been demonstrated to be effective for studying vascular bends in melanoma of the retina. However, it should be stressed that only a limited subset of tumors will be amenable to study in this manner. An absolute requirement for such a technique is a clear differentiation between the vascular structures of the tumor and surrounding tissues. If this clear differentiation is not present, then diffuse fluorescence from ICG in the vasculature of the surrounding tissue will mask fluorescence of ICG in vessels within the tumor. In other words, the zero background advantage of fluorescence techniques will be lost, reducing sensitivity and specificity.

In addition to providing contrast for studying vasculature, ICG has also been used in the investigation of burns.\(^{(25)}\) In contrast to the above studies, studies involving burns have focused upon the degree of ICG fluorescence recorded at various times after a burn was induced was correlated with clinical outcome of burns of various depths. Burns were produced in anesthetized pigs by placing a heated brass block on the skin. Burn depth was varied by varying the time of contact between the block and the skin. Following creation of the burn, a bolus of ICG was injected into the circulatory system at various time points, the skin illuminated at 780 nm and fluorescence images acquired using a CCD camera. Comparison of fluorescence in burns and adjacent normal tissue revealed interesting differences that could be related not only to the stage of the burn (i.e. time after the burn was created) but also to burn depth. Fluorescence images from deep burns (i.e. those produced by prolonged contact between heated metal block and the skin) showed a decreased fluorescence intensity at the burn site compared with superficial burns. This difference in fluorescence intensity was related to a decreased ICG content in deeper vessels in the deep burn. In superficial burns, such vessels remain largely intact, allowing ICG flow and a strong ICG fluorescence signal. In deep burns
these vessels are damaged and become occluded, reducing blood and ICG flow and reducing the fluorescence signal.

In addition to discriminating between burns of different thickness, ICG fluorescence imaging was also able to discriminate between fresh and older (24 h) burns. A significant (twofold) elevation of fluorescence intensity was seen in images of fresh burns compared with images of burns recorded after 24 h. This difference was attributed to an increase in capillary permeability in fresh burns, leading to an increased efflux of ICG from capillaries and accumulation in the extravascular space.

Finally, and perhaps most importantly, ICG fluorescence imaging was able to discriminate between burns which healed within 21 days and those which did not heal within 24 h. At all time points, ICG fluorescence images showed a higher fluorescence intensity in burns which healed within 21 days compared with those which did not heal. Presumably this difference may be explained at least in part by a greater blood flow (leading to a greater ICG fluorescence signal) in burns which would heal. This greater blood flow in burns that would heal would have two beneficial effects, namely delivery of an adequate supply of nutrients to the regenerating tissues and removal of toxic waste products.

3 IMMUNOFLUORESCENCE IMAGING

The examples discussed above share a common drawback: a lack of specificity. In addition, toxicity may pose difficulties. These problems can be alleviated with the use of more effective targeting strategies that do not require the use of potentially toxic compounds. The most promising of these alternative approaches is immunofluorescence imaging. Immunofluorescence techniques combine the sensitivity of fluorescence measurement methods with the specificity of immunochemistry, allowing highly specific detection of low concentrations of materials. Specificity is achieved with the use of an antibody specific to the material that the investigator wishes to detect, e.g. a cell surface antigen expressed uniquely by cancer cells. Exposure of cells to such an antibody labeled with a fluorescent dye results in accumulation of the labeled antibody only on the surface of cancer cells and not on the surface of normal cells. Detection of a fluorescence signal from samples therefore confirms the presence of malignant cells. Specificity is provided by the unique nature of antibody–antigen interactions, while low limits of detection are possible owing to the inherent sensitivity of fluorescence techniques.

Immunofluorescence techniques are of course related to radioimmunoassays. However, radiolabeled materials pose a human and environmental risk before, during and after use. Specialized precautions, equipment and training are required for their use. Immunofluorescence techniques eliminate the need for radionuclides and the associated specialized equipment, expertise and health and safety risks while maintaining sensitivity.

Success in immunofluorescence imaging depends upon the correct choice of antibody, fluorophore and detection system.

3.1 Choice of Antibody

3.1.1 General Properties of Antibodies

To be detectable by immunofluorescence techniques, a substance must be immunogenic when introduced into a host animal, i.e. capable of inducing an immune response, and this immune response must result in the production of antibodies. Such immunogenic substances are termed antigens. Compounds that are immunogenic have certain general characteristics that include the following: they are foreign to the immunized organism, generally of high molecular weight and chemically complex. Proteins are good examples of immunogenic compounds. When a protein is used as an immunogen, it induces an immune response that results in the production of antibodies that exhibit a remarkable specificity towards that protein.

Although the ideal condition for eliciting an immune response involves having foreign substances of high molecular weight that are chemically complex, situations exist in which an immune response can be mounted against simple compounds of low molecular weight. In these situations, the small compound is rendered immunogenic by chemical linkage to a high molecular weight substance such as a protein.

Following incubation of the antigen in a host animal, antibodies to the antigen may be isolated. Antibodies are globular glycoproteins produced by B-lymphocytes in response to the presence of foreign substances. Figure 1 shows the generalized structure of an antibody molecule. At the molecular level, antibody molecules are made up of four polypeptide chains, two identical light chains (25 000 Da) and two identical heavy chains (50 000 Da). The structure of the antibody molecule is stabilized by a number of disulfide bridges. There are two antigen-binding sites on each antibody molecule, each having both a constant and a variable region. This variable portion can adopt an apparently infinite variety of subtly different forms that allow it to bind specifically to a vast variety of antigens. Interaction of an antibody with an antigen is governed by noncovalent forces, including hydrophobic, electrostatic and van der Waals forces and hydrogen bonding.

The nature of the heavy chain components of the constant region of the antibody molecule determines the
Figure 1 Generalized structure of an antibody molecule.

physical properties of the antibody, and antibodies are grouped into five classes based upon these properties. The five functional classes of immunoglobulin (Ig) are IgA, IgM, IgG, IgE and IgD. The biological properties of each of these classes are unique. For example, IgE is the major class of Ig involved in allergy and binds with high affinity to mast cells; IgG is the only class of Ig that crosses the placenta, providing immunity to the fetus; IgA is the major antibody that is found in saliva and tears; IgM can activate other components of the immune system to rupture bacteria and other cells.\(^{39}\)

3.1.2 Monoclonal Versus Polyclonal Antibodies

Normal B-lymphocytes are each capable of producing an antibody to a specific antigen determinant (the region of the antigen recognized by the antibody) when activated. As antigens usually have multiple antigenic determinants, a mixture of antibodies is therefore produced in the serum of inoculated animals. Each activated B-lymphocyte forms a clonal population of cells in the spleen, which produce the same antibody as the parent cell. Thus, a polyclonal population of cells is found in the spleen, secreting a wide variety of antibodies. Even relatively simple antigens normally lead the generation of a mixture of antibodies with different specificities and affinities.\(^{39}\)

This problem of a heterogeneous antibody population can be eliminated with the production of monoclonal antibodies. By fusing the clonal B-lymphocytes from the spleen with immortal myeloma cells, a group of immortal, antibody-producing hybrids are produced. If individual hybrid cells are then harvested and grown in culture, each individual cell gives rise to a colony of clonal cells, and each cell in the colony secretes the same (monoclonal) antibody. The hybrid colonies are then screened to determine which colony produces the monoclonal antibody with the desired properties. This colony is then used to produce an essentially limitless supply of monoclonal antibody with the desired properties.

Molecular homogeneity and an abundant supply have revolutionized immunoassays. Monoclonal antibodies are not without disadvantages. Lower affinity and the special techniques required for production are the major disadvantages of monoclonal antibodies compared with polyclonal antibodies. However, low affinities can be overcome by the careful selection of high-affinity antibody-producing hybrids, and currently many monoclonal antibodies have affinities in the range \(10^{-10} - 10^{-12}\) L mol\(^{-1}\).\(^{40}\)

3.1.3 Antibody Fragments

In addition to the use of entire antibody molecules, fragments of antibodies may also be used in immunofluorescence experiments. Obviously, this must involve the use of the \(F_{\text{ab}}\) fragment (i.e. the variable, high-affinity binding region) rather than the \(F_c\) fragment (i.e. the constant, non-binding region) of the antibody. The main advantage in the use of antibody fragments rather than the entire antibody lies in the potential for increased delivery of antibody fragments to tumor sites in in vivo studies.

In vivo immunofluorescence studies are limited by the rate of antibody delivery to the binding site. In part, the rate of delivery is determined by the molecular weight of the antibody. The use of a relatively small fragment of an antibody (MW 30 000–40 000) rather than the entire antibody increases the rate of diffusion across capillary walls and into the body of the tumor.\(^{41}\) This increased rate of delivery of labelled material to the site of interest obviously improves the changes of the fluorescent label being detected.

3.2 Choice of Fluorophore

The following characteristics should be taken into consideration in selecting the appropriate fluorophore:

1. **Coupling properties.** Coupling of a fluorophore label to immunological reagents (antibodies or their fragments) is an absolute prerequisite for immunofluorescence imaging. The fluorophore must therefore contain a reactive chemical group or be capable of derivatization to introduce a reactive group such as an isothiocyanate or ester group. Importantly, coupling should not affect the affinity or specificity of labeled antibodies or result in diminished signals.

2. **Sensitivity.** The sensitivity of immunoassays is highly dependent upon the properties of the fluorophore used. To be useful a fluorescent dye must have a high...
quantum yield, i.e. the efficiency of conversion of light from the absorption wavelength to the emission wavelength must be high.

3. **Stability.** When linked to antibodies, fluorophores should be nonreactive to materials within the sample of interest. Labeled materials should also be stable for extended periods of time. Stable signal levels both from day to day and from experiment to experiment are required. Stable fluorophores decrease the need for frequent standardization. It should be noted that many fluorophores are sensitive to factors such as temperature and pH.

4. **Availability.** In order for a label to be accepted in research and in the clinical setting, a label should be readily available, conditions for labeling the antibody should be mild and easily optimized and labeling should be highly reproducible.

5. **Excitation and emission maxima.** The excitation and emission maxima of the fluorophore must also be considered. For example, absorption maxima should not be in spectral regions in which endogenous materials absorb strongly and emission maxima should not be in spectral regions where endogenous chromophores exhibit significant emission or absorption. In addition, the choice of absorption and emission maxima, and so fluorophore, depend upon whether the experiment is conducted in vitro or in vivo. For example, dyes such as fluorescein isothiocyanate (FITC) are commonly used in immunofluorescence studies in vitro. However, such dyes are excited by UV or visible light and fluoresce in the visible range of the electromagnetic spectrum. Unfortunately, visible light has limited penetration through tissues. This limited penetration obviously reduces the utility of the dyes for in vivo studies. In contrast, cyanine fluorochromes have emission maxima in the far-red spectral region. Blood and tissue are relatively transparent at such wavelengths, leading to enhanced transmission of light through tissues. Cyanine dyes such as Cy5 are therefore more suited to in vivo applications.

4 CHOICE OF DETECTION SYSTEMS

For in vivo detection of fluorescence using visible or NIR fluorophores, CCD camera systems equipped with the appropriate filters are the detector systems of choice.

4.1 Charge-coupled Device Cameras

The detection system of choice is the CCD camera. CCD cameras are available with two-dimensional arrays of detectors that allow two-dimensional images to be acquired at wavelengths in the visible and NIR regions. The advantages of such cameras include high quantum efficiency, low noise characteristics, flexibility and ruggedness. CCD cameras are available in many forms, with many types of sensing element to choose from. However, a two-dimensional array of silicon detectors will provide adequate response over the spectral range 200–1000 nm and allow the detection of most common chromophores.

4.2 Filter Selection

If the detection of fluorescence at a particular wavelength is required, then all other wavelengths must be prevented from reaching the imaging array. This wavelength selection can be achieved either with the use of fixed-wavelength filters such as band-pass or interference filters or by using LCTFs. Band-pass and interference filters allow light at predetermined wavelengths to be transmitted to the sensing element. If multiple wavelengths are of interest (i.e. if multiple antibodies labeled with different fluorophores are used), then a filter is required for each wavelength. The requirement for multiple filters is removed if LCTFs are used. As their name implies, LCTFs utilize liquid-crystal technology and have tunable transmission characteristics. The transmission window of the filter is set and changed electronically. Thus, images can be acquired at multiple wavelengths with no hardware adjustments. In addition to the time saving, LCTFs have the additional advantage that no moving parts are involved in wavelength selection, registration of images at different wavelengths is excellent.

4.3 Typical Experimental Set-up

A typical set-up for an immunofluorescence imaging experiment is shown in Figure 2. A CCD camera equipped
A computer-controlled LCTF for wavelength selection is attached to the zoom lens. An illumination source is positioned so as to provide even illumination over the sample area. The source may be a broadband (white light) source or may be monochromatic radiation provided by a laser diode. If laser diodes are the source of choice, then precautions must be taken owing to the intense nature of the radiation produced. Although laser diodes are essentially monochromatic, side lobes (i.e., lower intensity emission on either side of the main emission line) may be evident. Although such side lobes are much weaker than emission at the main emission wavelength, the intensity may still be sufficient to result in transmission of some light through the LCTF. To eliminate this possibility, a band-pass filter should be inserted between the source and sample to remove wavelengths which are not of interest.

As an additional precaution when high-intensity sources such as laser diodes are used, a band-pass filter should be placed in front of the LCTF to eliminate scattered light at the frequency of the laser diode.

5 IMMUNOFLUORESCENCE IMAGING OF TUMORS

5.1 Qualitative Analysis of Images

The experimental set-up described above was used to study the interaction of a fragment of an antitumor antibody labeled with Cy5 with tumor cells implanted in athymic mice. The antibody fragment was a fragment of a human monoclonal antibody to a cell surface antigen expressed by a wide variety of human cancer cells. The athymic mouse has two major advantages in such experiments. First, the athymic mouse is hairless. This alleviates potential problems due to scattering of light by hair, which would not only reduce the amount of excitation light reaching the area of interest but would also result in blurring at the fluorescence site. Second, the athymic mouse is immune compromised. As such it provides an excellent host for human tumor cells, which will not be rejected following implantation. The ability to monitor binding of the antibody fragment to human tumor cells is important if the antibody is of human origin. This raises an important, if obvious, issue in immunofluorescence experiments: the choice of model system requires thought. It is crucial that the antigen to which the antibody is raised is expressed in the system under investigation. For example, the use of a carcinogen-treated animal as a model system may be inappropriate when utilizing human antibodies. The antigens expressed in tumors induced by carcinogens in animal models may not be the same as those expressed in human tumors. Use of a model system that hosts human tumor cells is preferable.

With the correct choice of imaging system (including illumination source and filters), antibody, dye and model, imaging can be successfully performed. A visible image and images acquired at 670 nm (excitation maximum) and 720 nm (near the emission maximum) from a tumor-bearing mouse injected with the antibody–Cy5 complex are shown in Figure 3. The tumor can be clearly seen in the visible image (Figure 3a). Images acquired at 670 nm 2 h postinjection of the antibody–dye complex show no discernible features, as expected. However, images
acquired at 720 nm clearly show fluorescence at the site of the tumor and also in the region of the kidneys (Figure 3c), indicating uptake of the antibody–dye complex by the tumor and kidneys. No fluorescence is seen at the tumor site following injection of free dye or following injection of a labeled irrelevant (i.e. nonbinding) fragment. However, injection of both free dye and the labeled irrelevant fragment resulted in fluorescence in the region of the kidneys (not shown). Fluorescence was also noted in the bladder following injection of free dye, antibody–dye and irrelevant antibody–dye, due to accumulation of the dye prior to excretion in the urine. Fluorescence was not detected in the bladder 24 h postinjection.

The kinetics of antibody binding can be qualitatively monitored by examining images of a tumor-bearing mouse taken at a number of time points. Figure 4(a–g) shows visible and fluorescence images acquired at $t = 0$ (preinjection), 2, 6, 12, 24 and 48 h postinjection of antibody–dye. As expected, no fluorescence is seen at the site of the tumor or in the kidneys preinjection. However, fluorescence is clearly seen in both the tumor and kidneys 2 h postinjection. Fluorescence in the tumor peaks 24 h postinjection in this animal, whereas fluorescence in the kidneys peaks 6 h postinjection. At 48 h postinjection, fluorescence in the kidneys has largely disappeared, but fluorescence is still apparent at the tumor site. Peak fluorescence in the kidneys is much greater than the peak fluorescence in the tumor.

### 5.2 Quantitative Analysis of Images

Visual inspection of the fluorescence signal arising from the tumors and kidneys presents problems. First, it is difficult to detect subtle differences in fluorescence intensity by eye. Second, the perceived intensity of fluorescence in images depends upon scaling of the images. Variations

*Figure 4* (a) Visible and 720-nm images of a tumor-bearing nude mouse at (b) 0, (c) 2, (d) 6, (e) 12, (f) 24 and (g) 48 h postinjection of an antibody–Cy5.5.18 complex.
in scaling between images can therefore lead to artefactual changes in intensity that may mask true changes in fluorescence intensity. A more rigorous analysis requires a quantitative assessment of fluorescence intensity. To obtain qualitative information relating to fluorescence intensity in each image (composed of 256 × 256 pixels), the intensity at each pixel through the region of the image showing the maximum fluorescence intensity was extracted. This is illustrated in Figure 5(a–f). The fluorescence intensity at each pixel along the line shown in each image is plotted as a function of position for each image. Pixel 0 corresponds to the pixel at the top of the image and pixel 256 corresponds to the pixel at the bottom of the image. This sequence of images clearly shows accumulation of the antibody in the both the tumor and kidney beginning at 2 h postinjection. The second, sharp peak observed in Figure 5(b) arises from fluorescence in the left kidney, part of which is traversed by the line of pixels extracted. The intensity of fluorescence from the tumor increased over time, peaking 24 h postinjection. The fluorescence then rapidly declines, falling to about 5% of the peak fluorescence 48 h postinjection. Fluorescence intensity persists at about 5% of peak intensity 72 h postinjection.

Figure 5 Images acquired at 720 nm from a tumor-bearing mouse (a) 2, (b) 6, (c) 12, (d) 24, (e) 48 and (f) 72 h following injection of an antibody–Cy5.5.18 complex. The fluorescence intensity at each pixel on the line through the region of greatest fluorescence intensity for each image (shown in white) is plotted below each image.
5.3 Statistical Analysis of Images

The method discussed above allows the quantitation of fluorescence as a function of time in individual animals but does not allow data from different animals to be pooled for statistical analysis. To allow comparison between animals, data must be normalized in some manner. Quantitative data from tumors may be normalized by scaling all data from each animal with respect to data obtained at a predetermined time point. For example, data may be normalized to images obtained from each animal 2 h postinjection. In other words, all data at 6 h postinjection are expressed as a percentage of the fluorescence intensity seen at 2 h postinjection in the same mouse. The mean difference in fluorescence intensity compared with 2 h postinjection may then be calculated for each time point. The mean and standard deviation difference in fluorescence relative to 2 h postinjection may then be calculated for each time point and analyzed using straightforward tests such as the paired difference test to assess statistically significant differences.

For the experiments described above the mean decrease in fluorescence seen 6 h postinjection (40%) was found to be significant \( p < 0.05 \). Fluorescence continued to decrease over time, reaching a minimum 72 h postinjection, with a mean decrease in fluorescence of 75%.

Figure 6(a–f) shows a series of images obtained from a control mouse, demonstrating uptake of the antibody–Cy5 complex by the kidneys as a function of time. In this example, the left kidney is masked and only the right kidney is monitored. Fluorescence from the complex can be seen at all time points measured. Uptake of the complex peaked at 6–12 h (Figure 6b, c) and then diminished with time, reaching a minimum at 72 h postinjection.

Data from kidneys were also normalized and analyzed using the paired difference test. Peak fluorescence occurred 6 h postinjection in the majority of animals and so data were normalized with respect to measurements made 6 h postinjection. The mean difference in fluorescence 2 h postinjection compared with 6 h postinjection (10%) was not significant. A nonsignificant decrease of only 24% \( p > 0.05 \) was seen 12 h postinjection. However, fluorescence significantly decreased 24, 48 and 72 h postinjection \( p < 0.05 \).

6 SUMMARY AND FUTURE PROSPECTS

A number of fluorescence imaging techniques show diagnostic promise. Imaging endogenous fluorescence has been proposed as a method for cancer diagnosis. Typically such studies rely on the decrease in the NADH/NAD\(^+\) ratio observed in malignant tissues, which results in a decreased fluorescence signal in malignant tissue. Unfortunately, tissue autofluorescence (whether from NADH or other endogenous chromophores) is relatively weak and poor contrast between malignant and normal tissue is seen. Contrast may be enhanced with the addition of fluorescent materials that are selectively accumulated by malignant cells, such as fluorescein or porphyrin derivatives. Although fluorescence from these chromophores occurs in the visible region of the spectrum, the limited penetration of light at these wavelengths restricts the use of fluorescence techniques.
**Figure 6** Images acquired at 720 nm from a control mouse (a) 2, (b) 6, (c) 12, (d) 24, (e) 48 and (f) 72 h following injection of an antibody–Cy5.5.18 complex. The fluorescence intensity at each pixel on the line through the region of greatest fluorescence intensity for each image (shown in white) is plotted below each image.
utilizing these chromophores to superficial phenomena. However, many potential applications still exist. For example, monitoring fluorescein fluorescence during surgery may allow resection margins to be clearly delineated.

Other exogenous chromophores that may have diagnostic utility include ICG. Techniques based upon visualization of the distribution of ICG fluorescence (i.e. choroidal angiography) are already prominent in ophthalmology. As discussed above, ICG fluorescence imaging may also find a useful niche in monitoring of burns and transplant tissue. Two features are common to each of these applications: distribution of fluorescence at an accessible surface is monitored and the main phenomena under investigations related to microvascular circulation. Obviously the requirement for an accessible surface limits non-invasive diagnostic applications. However, monitoring of vascular parameters during cardiac surgery presents exciting opportunities. For example, low oxygen levels (e.g. during bypass surgery) in the heart can result in alterations in microvascular permeability. As ICG is largely bound to serum albumin, it should not be seen in extravascular spaces in normal hearts and ICG fluorescence will be seen only in blood vessels. However, increased permeability will allow albumin to diffuse into the extravascular spaces, and diffuse fluorescence across the surface of the heart will be seen. In principle, the infusion of polymers (e.g. dextrans) of various molecular weights labeled with dyes that fluoresce at different wavelengths will allow the assessment of the porosity of capillary beds in such systems.

Imaging ICG fluorescence may also be useful in detecting atherosclerotic plaques in superficial vessels such as the carotid artery in the neck, a major site of plaque formation. Regions of plaque formation should in principle appear as areas of vessels with a narrow fluorescence profile.

ICG is largely cleared from the blood by the liver. However, it has been demonstrated that areas of the liver affected by hepatocellular carcinoma show decreased uptake of ICG. Clearly this reduced uptake of ICG has diagnostic implications, and again may prove useful for determining tumor boundaries during surgery.

Immunofluorescence techniques have the potential to provide unmatched sensitivity and specificity. The unique nature of antibody–antigen interactions ensures specific delivery of the fluorophore to the site of interest. Most studies to date have been limited, but the potential should be apparent. The specific interaction of labeled antibodies with antigens means that the fluorophore persists in the body for a prolonged period of time (days). Following a single injection of labeled antibody, repeated measurements on the same site over the course of hours or days allow kinetic information to be readily obtained. In principle this means that the effect of therapeutic intervention, i.e. radiation therapy, chemotherapy, etc., can be monitored. This would be achieved by comparing an initial fluorescence image acquired immediately prior to treatment with images obtained as treatment progressed.

The clinical potential of fluorescence imaging techniques is only now becoming apparent. Advances in instrumentation and continued development of new chromophores are opening up new possibilities and it is surely only a matter of time before fluorescence imaging techniques become established clinical tools.

Diagnostic techniques based on optical spectroscopy have the potential to link the biochemical and morphological properties of tissues to individual patient care. In particular, these techniques are fast, noninvasive and quantitative. Furthermore, they can be used to elucidate key tissue features, such as the cellular metabolic rate, vascularity, intravascular oxygenation and alterations in tissue morphology. These tissue features can be interpreted to shed light on a variety of clinical problems, such as precancerous and cancerous growth and atherosclerosis. The goal of this report is to review the development and application of optical spectroscopy in the ultraviolet (UV) and visible (VIS) spectral regions, as a diagnostic tool in clinical applications. A particular emphasis is placed on steady-state, UV/VIS fluorescence spectroscopy for the detection of precancers and cancers, in vivo.

1 FLUORESCENCE SPECTROSCOPY

1.1 Introduction

Diagnostic techniques based on optical spectroscopy have the potential to link the biochemical and morphological properties of tissues to individual patient care. In particular, these techniques are fast, noninvasive and quantitative. Furthermore, they can be used to elucidate key tissue features, such as the cellular metabolic rate, vascularity, intravascular oxygenation and alterations in tissue morphology. These tissue features can be interpreted to shed light on a variety of clinical problems, such as precancerous and cancerous growth and atherosclerosis. Applied successfully, optical spectroscopy has the potential to represent an important step forward toward advances in diagnostic and therapeutic medical applications.

Spectroscopy is the study of the interaction of electromagnetic radiation with matter. There are three aspects to a spectroscopic measurement: irradiation of a sample with electromagnetic radiation; measurement of the absorption, spontaneous emission (fluorescence, phosphorescence) and/or scattering (Rayleigh elastic...
The goal of this article is to review the development and application of UV/VIS optical spectroscopy as a diagnostic tool in clinical applications. Particular emphasis is placed on steady-state UV/VIS fluorescence spectroscopy for the detection of precancers and cancers in vivo. In this section the principles and definitions that are related to the phenomenon of fluorescence are summarized. In the next section the endogenous fluorescence properties of molecules present in cells and tissues and the fluorescence properties of exogenous molecules, which can be used as contrast agents, are presented. This is followed in section 3 by a discussion of the effect of absorption and scattering on fluorescence spectroscopy of turbid media such as tissue, and methods for deconvolving this effect. Next, the instrumentation requirements for fluorescence spectroscopy of tissues are reviewed in section 4. In the last several sections, a summary of the clinical applications of fluorescence spectroscopy, particularly precancer and cancer detection (section 5), a review of representative instruments (section 6) and methods of analysis used (section 7) are presented. With respect to methods of analysis, statistical models, which are used solely for the purpose of discriminating diseased from nondiseased tissues based on the spectral information, as well as physical models, which have the potential to elucidate the biochemical/morphological basis for the spectral differences observed, are presented. In the final part of section 7, the effect of the illumination and collection geometry on fluorescence spectroscopy of tissues is discussed and approaches to resolve it are presented. This article concludes with a brief discussion of future perspectives in section 8.

1.2 Principles and Definitions

1.2.1 Probing Energy Levels with Electromagnetic Radiation

Optical spectroscopy probes the energy levels of a molecule. The energy level of a molecule is defined as its characteristic state, which is related to the molecular structure of the molecule and to the energetics and dynamics of any chemical processes that the molecule may undergo. The ground state of a molecule is defined as the state of lowest energy. States of higher energy are called excited states. A molecule possesses several distinct reservoirs of energy levels, including electronic, vibrational, rotational, translational and those associated with nuclear and electron spin. In the optical regime, the energy levels of interest are those that are associated with vibrational and electronic transitions. The separation between vibrational energy levels is determined by the mass of the atoms and the flexibility of the chemical bonds joining them. The separation between electronic

scattering. Raman inelastic scattering) from the sample; and analysis and interpretation of these measurements. Detailed study of absorption, spontaneous emission and scattering provides information that can be classified broadly as analytical, structural, dynamic, and energetic.

Optical spectroscopy deals with interactions of electromagnetic radiation with matter that occur at the UV, VIS, near-infrared (NIR) and infrared (IR) wavelengths. In the UV/VIS spectral regions (<700 nm), light can penetrate only superficial tissue volumes (a few hundred microns to a millimeter in depth) due to the fact that this biological medium is highly absorbing. However, in the NIR spectral region (700–900 nm) tissue is generally less absorbing and, furthermore, the number of elastic scattering events of light in tissue is approximately two orders of magnitude greater than the number of absorption events. This enables the light to propagate through tissue volumes that are up to several centimeters in depth. In the UV/VIS spectral regions, absorption and fluorescence spectroscopy have been explored extensively as diagnostic tools for precancer and cancer detection in the surface epithelia of various organ sites (colon, cervix, bronchus, lung, bladder, brain, esophagus, head and neck, skin, bile duct, breast and stomach tissues) and for the characterization of atherosclerosis in the surface of artery vessel walls. Recently, fluorescence spectroscopy was also used to detect Alzheimer’s disease of the brain in vitro. Elastic scattering spectroscopy in this spectral region also has been evaluated for the detection of precancers and cancers in the surface epithelia of several organ sites, but to a much lesser extent.

NIR absorption, fluorescence and phosphorescence spectroscopies have been used to interrogate larger tissue volumes. In particular, NIR absorption has been used to detect brain bleeds, brain oxygenation, functional activity of the brain, bioenergetics of skeletal muscle (e.g. in the case of genetic disease of mitochondrial function) and breast tumors. NIR correlation spectroscopy, which monitors fluctuations in the elastic scatter intensity, is emerging as a potential diagnostic tool to detect blood flow deep within thick tissue.

To date, most clinical applications have concentrated on absorption, fluorescence and elastic scattering spectroscopies, because these measurements can be obtained with a good signal-to-noise ratio in reasonably short integration times. However, with advances in illumination and detection technologies, NIR Raman scattering, which is a relatively weak phenomenon, is emerging as a potential diagnostic tool for precancer and cancer detection in the surface epithelia of various organ sites for the characterization of atherosclerosis on the surface of artery vessel walls and for glucose monitoring.
energy levels, which is greater, occurs when electrons are displaced from one region of a molecule to another.

At any finite temperature, the molecules will be distributed among the energy levels available to them because of thermal agitation.\(^{(2)}\) The exact distribution will depend on the temperature \((T)\) and on the separation between the energy levels \((\Delta E)\) in the energy ladder. At a given temperature, the number of molecules in an upper level \((n_{\text{upper}})\) relative to that in a lower level \((n_{\text{lower}})\) is given by the Boltzmann distribution, as shown in Equation (1):

\[
\frac{n_{\text{upper}}}{n_{\text{lower}}} = \exp \left( \frac{-\Delta E}{kT} \right) \tag{1}
\]

where \(k\) is the Boltzmann constant \((1.38 \times 10^{-23} \text{ J K}^{-1})\). When electromagnetic radiation is applied to a molecule, it is just as likely to cause transitions from a higher to a lower energy level as it is to cause transitions from a lower to a higher energy level. Consequently, net absorption or transition to a higher energy level can occur only if the difference between the populations of the energy levels concerned is significant, with the lower one being significantly higher. Calculation of the population of energy levels at room temperature\(^{(2)}\) has shown that for vibrational energy level spacings the ratio \(n_{\text{upper}}/n_{\text{lower}}\) is \(\sim 10^{-3}\) and for electronic energy level spacings it is \(10^{-21}\).

### 1.2.2 The Fluorescence Phenomenon

Figure 1 displays an energy level diagram with ground \((S_0)\) and excited \((S_1)\) electronic states as well as vibrational energy levels within each electronic state of a molecule.\(^{(26)}\) When a molecule is illuminated at an excitation wavelength that lies within the absorption spectrum of that molecule, it will absorb the energy and be activated from its ground state \((S_0)\) to an excited singlet state \((S_1)\), with the electron in the same spin as its ground state. The molecule can then relax back from the excited state to the ground state by generating energy either nonradiatively or radiatively, depending on the local environment. In a nonradiative transition, relaxation occurs by thermal generation (dashed arrows). In a radiative transition, relaxation occurs via fluorescence at specific emission wavelengths (solid arrow). Fluorescence generation occurs in three steps: thermal equilibrium is achieved rapidly as the electron makes a nonradiative transition to the lowest vibrational level of the first excited state; the electron then makes a radiative transition to a vibrational level of the ground state; and finally the electron makes a nonradiative transition to the lowest vibrational level of the ground state. When there is inter-system crossing, in which the spin of the electron is flipped in the excited state, the time for radiative transition from the excited state to ground state is longer because the transition must occur with a spin change. This excited state is termed the triplet state (not shown). Radiative transition from the excited triplet state is termed phosphorescence. Tissue absorption, fluorescence and phosphorescence monitor changes in electronic energy levels, to provide biochemical information from biological molecules.

The phenomenon of fluorescence displays several general characteristics for a particular biological molecule.\(^{(26)}\) First, due to the losses in energy between absorption and emission that occur as a result of nonradiative transitions, fluorescence occurs at emission wavelengths that are always red-shifted relative to the excitation wavelength. Second, the emission wavelengths are independent of the excitation wavelength. Third, the fluorescence spectrum of a biological molecule is generally a mirror image of its absorption spectrum.

The fluorescence of a biological molecule is characterized by its quantum yield and its lifetime.\(^{(26)}\) The quantum yield is simply the ratio of the number of photons emitted to the number absorbed. The lifetime is defined as the average time the biological molecule spends in the excited state prior to return to the ground state. The fluorescence quantum yield and lifetime are modified by a number of factors that can increase or decrease the energy losses. For example, a molecule may be nonfluorescent as a result of a large rate of nonradiative decay (thermal generation) or a slow rate of radiative decay (fluorescence generation).

Fluorescence spectroscopy is the measurement and analysis of various features that are related to the fluorescence quantum yield and/or lifetime of a biological molecule. The fluorescence intensity of a biological molecule is a function of its concentration, its extinction coefficient (absorbing power) at the excitation wavelength, and its quantum yield at the emission wavelength.\(^{(2)}\) A fluorescence emission spectrum represents the fluorescence intensity measured over a range of emission wavelengths at a fixed excitation wavelength. On the other hand, a fluorescence excitation spectrum is a plot of the fluorescence intensity at a particular emission wavelength for a range of excitation wavelengths.
A fluorescence excitation–emission matrix (EEM) is a two-dimensional contour plot that displays the fluorescence intensities as a function of a range of excitation and emission wavelengths. Each contour represents points of equal fluorescence intensity. Figure 2 illustrates a fluorescence emission spectrum (Figure 2a), a fluorescence excitation spectrum (Figure 2b) and a fluorescence EEM (Figure 2c).

2 FLUOROPHORES

2.1 Endogenous Fluorophores

Table 1 lists the biological molecules that exhibit endogenous fluorescence, along with their excitation and emission maxima. These endogenous fluorophores include amino acids, structural proteins, enzymes and co-enzymes, vitamins, lipids and porphyrins. Their excitation maxima lie in the range 250–450 nm (spanning the UV/VIS spectral range), whereas their emission maxima lie in the range 280–700 nm (spanning the UV/VIS/NIR spectral range). Details of the molar extinction coefficients, fluorescence quantum yields and lifetimes are provided elsewhere. The endogenous fluorophores that are speculated to play a role in transformations that occur with carcinogenesis are the amino acids tryptophan and tyrosine, the structural proteins collagen and elastin, the coenzymes NADH and FAD, and porphyrins.

FAD, flavin adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NAD(P)H, reduced nicotinamide adenine dinucleotide phosphate.

2.1.1 Amino Acids: Tryptophan and Tyrosine

Amino acids are the basic structural units of a protein and proteins play crucial roles in virtually all of the biological processes. Three amino acids with aromatic side chains are fluorescent. At excitation wavelengths above 295 nm only tryptophan is fluorescent. From 280 to 295 nm, both tyrosine and tryptophan are fluorescent; however, energy transfer from tryptophan to tyrosine is common. Below 280 nm, all three amino acids can be excited, albeit the quantum yield of phenylalanine is relatively low compared with that of tryptophan and tyrosine.

2.1.2 Structural Proteins: Collagen and Elastin

Collagen, a family of fibrous proteins, is distinctive in forming insoluble fibers that have a high tensile strength. It is the major extracellular matrix component that is present to some extent in nearly all organs.
and serves to hold cells together in discrete units. Elastin is the major component of elastic fibers and is found in most connective tissues in conjunction with collagen and polysaccharides.\(^{(40)}\)

Fluorescence has been noted from collagen\(^{(41)}\) and elastin.\(^{(42)}\) Collagen fluorescence in load-bearing tissues is associated with cross-links, hydroxylsyl pyridoline and lysyl pyridinoline.\(^{(43)}\) Collagen fluorescence has an excitation maximum at 325 nm and an emission maximum at 400 nm, as displayed in Figure 3.\(^{(41)}\) The fluorescent material in elastin is a tricarboxylic triamino pyridinium derivative, which is very similar in spectral properties to the fluorophore in collagen.\(^{(44)}\) The excitation and emission maxima of the fluorescence of this elastin cross-link occur at 320 and 405 nm, respectively, as shown in Figure 4.\(^{(42)}\)

### 2.1.3 Metabolic Coenzymes: Pyridine Nucleotides and Flavoproteins

Living organisms require a continual input of free energy through cellular metabolism for the performance of mechanical work in muscle contraction and other cellular movements, the active transport of molecules and ions, and the synthesis of macromolecules and other biomolecules from simple precursors.\(^{(40)}\) In most processes, the carrier of free energy is adenosine triphosphate (ATP), which is derived from the oxidation of fuel molecules such as carbohydrates and fatty acids. In aerobic organisms, the ultimate oxidizing agent or electron acceptor is molecular oxygen. However, electrons are not transferred directly from fuel molecules and their breakdown products to molecular oxygen. Instead, these substrates transfer electrons to special carriers called pyridine nucleotide (PN) and flavoprotein (Fp). The oxidized form of PN – nicotinamide adenine dinucleotide (NAD\(^+\)) – and the oxidized form of Fp/FAD – are the major electron acceptors in the oxidation of fuel molecules. After accepting the electrons, these carriers become reduced. The now reduced electron carriers – NADH and reduced flavin adenine dinucleotide (FADH\(_2\)) – then transfer their electrons to molecular oxygen by means of the electron transport chain in the inner membrane of the mitochondria within the cell. As a result, molecular oxygen oxidizes them to NAD\(^+\) and FAD. The ultimate flow of these electrons to molecular oxygen drives the synthesis of ATP.

The fluorescent forms of these electron carriers are the reduced form of PN and the oxidized form of Fp, which emit fluorescence when excited with UV and blue light respectively. Figure 5 displays the fluorescence excitation and emission spectra of Fp and PN from isolated pigeon heart mitochondria measured at –196 °C.\(^{(45)}\) Figure 5(a) and (b) displays the oxidized (Ox) and reduced (Red) Fp excitation and emission spectra, respectively, and Figure 5(c) and (d) shows the oxidized (Ox) and reduced (Red) PN excitation and emission spectra, respectively. Clearly, the excitation and emission of Fp is maximal when it is oxidized and minimal when it is reduced. The converse is true for PN. The ratio of the concentration of oxidized and reduced electron carriers (or, synonymously, the ratio of the fluorescence of Fp and PN) gives a measure of the cellular metabolic rate.\(^{(45)}\) In particular, a reduced

Fluorescence microscopy and spectroscopy of fluores-

2.1.5 Fluorescence Microscopy and Spectroscopy of

2.1.4 Porphyrins

Porphyrin is a precursor in heme biosynthesis. It leads to the synthesis of protoporphyrin IX (PpIX), which acquires an atom to form heme. δ-Aminolevulinate synthase, the enzyme catalyzing the committed step in this pathway, is feedback inhibited by heme. Porphyrians produce a red fluorescence, with peaks at 630 and 690 nm, when excited in the blue spectral region between 400 and 450 nm.

2.1.5 Fluorescence Microscopy and Spectroscopy of

Microstructures in Cultured Cells and Tissue

Sections

Fluorescence microscopy and spectroscopy of fluorescent micro-structures in cultured cells and optically thin, unstained, frozen tissue sections have indicated that differences in the fluorescence emission spectra of normal,

precancerous and cancerous tissues may be attributed to differences associated with several endogenous fluorophores within the various sublayers of these tissues. Pradhan et al. suggested that there is an increase in NADH and tryptophan, whereas Anidjar et al. reported that there is probably a decrease in FAD as cells progress from a normal to cancerous state. Romer et al. and Fairman et al. observed a decreased fluorescence intensity from the collagens in precancerous colon tissue sections relative to that in normal colon tissue sections. Bottirol et al. observed a red fluorescence in some parts of a tissue section that was from a cancerous colon. The red fluorescence that was observed by Bottirol et al. has been observed previously by several groups.

2.2 Exogenous Fluorophores

Most exogenous fluorophores currently being evaluated as contrast agents for precancer and cancer detection include photosensitizers, developed originally for photodynamic therapy (PDT). These include hematoporphyrin derivative (HpD), phorphorbide-a, meso-tetra-(hydroxyphenyl)-chlorin (MTHPC), benzoporphyrin derivative (BPD), tin etiopurpurin (SnET2), hypercin and phthalocyanine. These compounds have strong absorption characteristics in the blue spectral region or up to the highest Q-band at 635 nm, resulting in fluorescence between 625 and 675 nm. These agents are generally administered systemically and the difference in accumulation of these exogenous fluorophores in tumor tissue relative to their normal counterpart appears to correlate with the differences in the vascularity of the two tissue types. Lutetium texaphyrin is another photosensitizing agent that has absorption and fluorescence characteristics in the blue spectral region. This agent seems to be selectively phototoxic to tumors via apoptosis rather than necrosis (which results from vascular stasis), suggesting that this agent localizes in the cell. During the past few years an alternative concept has been introduced, which is based on the initial observations of Ghadially et al., who suggested using the photosensitizing precursor δ-aminolevulinic acid (5-ALA) to induce PpIX fluorescence in tumors. PpIX is characterized by an absorption maximum at 405 nm and fluorescence maxima at 630 and 700 nm. The compound 5-ALA is a natural precursor of PpIX in the biosynthetic pathway for heme. Normally, the synthesis of heme regulates the synthesis of PpIX through feedback control. However, the administration of 5-ALA bypasses this feedback and induces the accumulation of PpIX in tumor tissue. It has been suggested that deficiency in ferrochelatase (the enzyme required for conversion of PpIX to heme) in tumors results in accumulation of PpIX.
in these tissues relative to normal tissue.\textsuperscript{(12)} There are several advantages associated with using 5-ALA as a contrast agent. Both 5-ALA and PpIX are substances naturally present in the body, making the toxicity issue less critical. Furthermore, the drug can be administered conveniently both orally and topically.\textsuperscript{(12)}

The use of photosensitizers as purely contrast agents has raised potential safety and toxicity concerns. Hence, recent work has examined nonphotosensitizing agents with similar absorption and fluorescence characteristics to photosensitizers for their potential to serve as contrast agents. Several exogenous fluorophores, including Nile blue and its derivatives and the caretenoporphyrins, have been shown to fulfil this criterion.\textsuperscript{(12)} Nonphotosensitizing or weakly phototoxic exogenous fluorophores that are in routine clinical use currently are fluorescin (fluorescent angiography) and indocyanine green (cardiac output measurements and liver assessment), which have absorption and fluorescence characteristics in the VIS and NIR regions, respectively.\textsuperscript{(11)} In clinical use, these drugs are injected into the vasculature, through which they are ultimately cleared.

3 FLUORESCENCE SPECTROSCOPY OF TURBID MEDIA

3.1 Fluorescence Spectroscopy of an Optically Dilute, Homogeneous Medium

Using the Beer–Lambert law,\textsuperscript{(2)} one can express the fluorescence intensity of an optically dilute, homogeneous medium (sum of the optical densities at the excitation and emission wavelengths. Everywhere is less than unity)\textsuperscript{(26)} as a linear function of the concentration of the fluorophores in that medium. Specifically, the fluorescence intensity, $F(\lambda_x, \lambda_m)$, at particular excitation ($\lambda_x$) and emission ($\lambda_m$) wavelengths due to $k$ fluorophores is defined according to Equation (2):

$$F(\lambda_x, \lambda_m) = P_0(\lambda_x) \frac{L}{\Omega} \sum_{k=1}^{N} \mu_a(\lambda_x) \phi_k(\lambda_m)$$

and Equation (3) gives the definition of $\mu_a(\lambda_x)$, the absorption coefficient of the fluorophore at the excitation wavelength:

$$\mu_a(\lambda_x) = 2.303 \varepsilon(\lambda_x) C$$

In Equations (2) and (3) $\phi(\lambda_m)$ is the quantum yield of the fluorophore at the emission wavelength, $P_0(\lambda_x)$ is the power of the intensity at the excitation wavelength, $L$ is the path length and $\Omega$ is the detector collection efficiency. The absorption coefficient $\mu_a(\lambda_x)$ is a linear function of $\varepsilon(\lambda_x)$ and $C$, which are the extinction coefficients at excitation wavelength and concentration, respectively, of the fluorophore. Although fluorescence spectroscopy of optically dilute, homogeneous media is well understood, fluorescence spectroscopy of turbid media, such as human tissue, is complicated by its highly absorbing and scattering properties.\textsuperscript{(13)}

3.2 Fluorescence Spectroscopy of Turbid Media such as Tissue

Fluorescence spectroscopy of turbid media such as tissue depends on one or more of the following. Specifically, it depends on the concentration and distribution of fluorophore(s) present in the tissue as well as the biochemical/biophysical environment, which may alter the quantum yield and lifetime of the fluorophore(s). For example, epithelial tissues generally have two primary sublayers – a surface epithelium and an underlying stroma or submucosa; the specific fluorophores, as well as their concentration and distribution, can vary significantly between these two tissue layers. Fluorescence spectroscopy of turbid media such as tissue also depends on the absorption and scattering that result from the concentration and distribution of nonfluorescent absorbers and scatterers, respectively, within the different sublayers of the tissue.

The effect of the aforementioned variables on fluorescence spectroscopy of tissue is wavelength dependent. First, the endogenous fluorophores that have absorption bands that lie in the same wavelength range as the excitation light will be excited and hence will emit fluorescence. The absorption and scattering properties of the tissue will affect light at both of these excitation and emission wavelengths. Therefore only those fluorophores contained in the tissue layers to which the excitation light penetrates and from which the emitted light can escape the tissue surface will produce measurable fluorescence. Elastic scattering events in tissue are caused by random spatial variations in the density, refractive index and dielectric constants of extracellular, cellular and subcellular components.\textsuperscript{(54)} Tissue scattering generally decreases monotonically with increasing wavelength over the UV, VIS and NIR spectral regions.\textsuperscript{(11)} Tissues are generally forward scattering (mean anisotropy factor is between 0.97 and 0.98), with scattering coefficients ranging from 10 to 1000 cm$^{-1}$ from the NIR to the UV spectral range.\textsuperscript{(11)} Absorption in tissue in the UV, VIS and NIR regions is primarily attributed to hemoglobin.\textsuperscript{(55)} Although absorption in tissue is strongly wavelength dependent, it tends to decrease generally with increasing wavelengths.\textsuperscript{(11)} Typically, tissue absorption coefficients range from 0.1 to 10 000 cm$^{-1}$ from the NIR to the UV spectral range. Consequently, the penetration depth of light, which is primarily a function of the tissue absorption properties,
decreases from several centimeters to a few hundred microns from the NIR to the UV. For example, in the UV spectral region, the penetration depth of light in tissue is approximately 225 µm at 337 nm. Hemoglobin, which is contained in red blood cells, serves as the oxygen carrier in blood and also plays a vital role in the transport of carbon dioxide and hydrogen ions. The capacity of hemoglobin to bind oxygen depends on the presence of a nonpolypeptide unit, namely a heme group. The heme consists of an organic part, a protoporphyrin ring and an iron atom. Figure 6 displays the absorption spectra of oxygenated and deoxygenated hemoglobin over the UV/VIS (Figure 6a) and NIR (Figure 6b) spectral regions. In Figure 6(a), the absorption spectra are characterized by the Soret band at 400–450 nm, the bands at 540 (α band) and 569 nm (β band) of oxygenated hemoglobin and the 557 nm band of deoxygenated hemoglobin. In Figure 6(b), the absorption spectra are characterized by the decreasing absorption of deoxygenated hemoglobin and the increasing absorption of oxygenated hemoglobin as a function of increasing wavelength.

The effect of hemoglobin absorption is noticeable when comparing fluorescence emission spectra measured from an optically thick arterial tissue sample (250 µm thickness) to that measured from a corresponding, optically thin tissue section (4 µm thickness) using the same illumination and collection geometry, as shown in Figure 7. Evaluation of Figure 7 indicates that the fluorescence intensity of the optically thick tissue sample is significantly reduced and, furthermore, its line shape is characterized by a valley at 420 nm, which corresponds to the Soret absorption band of hemoglobin. The fluorescence emission spectrum of the optically thin tissue section may be attributed to collagen fluorescence.

The illumination and collection geometry of the excitation and the emitted light, respectively, can also affect fluorescence measurements from tissue with respect to both the intensity and line shape. This may be attributed to the fact that although fluorescence is generated isotropically from the fluorophores within the...
biological medium, the fluorescence emitted from the surface of the medium may range from isotropic to anisotropic, depending on whether the medium is highly absorbing, dilute or turbid.\(^{(54)}\) Monte-Carlo simulations have been used extensively to simulate light distribution in turbid media to explore the effect of absorption and scattering on the fluorescence emitted from the surface of tissues using finite excitation beam profiles and complex excitation and emission geometries.\(^{(57)}\) The results of these simulations indicate several important findings.

The profile of the excitation beam greatly affects the distribution of the excitation light in the tissue and thus is an important factor. For a Gaussian beam profile, the fluorescence distribution at a specific emission wavelength on the surface of the tissue is peaked and narrow, whereas for a uniform profile it is wider and less peaked. Furthermore, the effect of absorption, particularly due to hemoglobin, on the measured fluorescence increases as the collection fiber is moved further away from the illumination fiber on the surface of the tissue, resulting in decreased fluorescence intensity. In addition, the effect of this absorption is wavelength dependent, suggesting that it will affect the line shape of the fluorescence as well. This is evident when comparing the fluorescence emitted at two wavelengths at which hemoglobin has different absorption characteristics. As the distance of the collection fiber increases relative to the illumination fiber, the ratio of the fluorescence intensity at 600 and 580 nm is 1.27, whereas it is 1.72 in Figure 8(b). For the atheromatous tissue, the ratio is 0.91 for both collection areas.

### 3.3 Deconvolution of Absorption and Scattering from Tissue Fluorescence Emission Spectra

Fluorescence excitation and emission from turbid media such as tissues consist of three components: the distribution of the excitation light in the tissue, which is a function of the absorption and scattering coefficients of the medium at that wavelength; the fluorescence of isotropically radiating point sources located at different depths within the tissue, which is determined by the fluorescence quantum yield of the fluorophore and the excitation intensity at that depth; and the total fluorescence escaping the surface of the tissue, which is a function of the absorption and scattering properties of the medium at that wavelength. Quantification of the concentration of fluorophores within tissue in principle involves deconvoluting the absorption and scattering properties of the tissue from the measured fluorescence emission spectrum and quantifying the identity and distribution of the fluorophores that contribute to the deconvolved spectrum. The former requires the development of a transfer function based on the measurements of tissue optical properties, i.e. the absorption and scattering coefficients and the anisotropy parameter, whereas the latter requires knowledge of the identity and distribution of the fluorophores within the tissue.

---

**Figure 8** Fluorescence emission spectra at 476 nm excitation of normal human cadaver aorta (N) and of one with atheromatous plaque (P).\(^{(58)}\) In Figure 8(a) fluorescence was collected from the tissue site directly illuminated by the excitation light, and in Figure 8(b) the fluorescence was collected from a circular area around the directly illuminated area. Both the intensity and line shape of the fluorescence are affected by the probe geometry. For the normal aorta (Figure 8a) the ratio of the fluorescence intensity at 600 and 580 nm is 1.27, whereas it is 1.72 in Figure 8(b). For the atheromatous tissue, the ratio is 0.91 for both collection areas.
For a turbid medium such as tissue that contains $k$ fluorophores, the fluorescence intensity can be rewritten to include a transfer function ($TF$) that describes the attenuation of the excited and emitted light due to the absorption and scattering properties of the tissue at these wavelengths. This is defined in Equation (4):

$$ F(\lambda_x, \lambda_m) = P_0(\lambda_x) \sum_{k=1}^{N} \mu_{\text{abs}}(\lambda_x, z)\phi_k(\lambda_m, z) \times TF(\lambda_x, \lambda_m, z) \Omega $$

where $z$ refers to the depth within the medium. Here, the transfer function for a particular depth can be determined from the tissue absorption coefficient, the scattering coefficient and the anisotropy factor. The wavelength-dependent absorption coefficient ($\mu_a$) denotes the probability of photon absorption per unit path length, whereas the scattering coefficient ($\mu_s$) denotes the probability of photon scattering per unit path length. The anisotropy factor ($g$) denotes the cosine of the average scattering angle. The reduced or isotropic scattering coefficient ($\mu'_s$) is the product of the scattering coefficient ($\mu_s$) and one minus the anisotropy parameter $(1 - g)$. Models of light transport can be used to deduce the absorption and scattering coefficients and the anisotropy parameter needed to compute the transfer function in Equation (4).

### 3.3.1 Models of Light Transport

Most models of light transport used to quantify tissue optical properties to date have been either numerical or approximate analytical solutions of the neutral particle transport equation. Because of the inhomogeneity of tissues, the solution of Maxwell’s equations, which might otherwise be used to model light propagation in tissues, is generally not feasible. However, if polarization and diffraction effects are ignored, the transport of photons through random media may be modeled as neutral particle transport. The neutral particle transport theory is heuristic and is based on a statistical approximation of photon transport in a multiple-scattering medium. Within this framework, the propagation of light is described in terms of the transport of discrete photons, which may be either scattered or absorbed. The transport equation (Equation 5) is defined as:

$$ -\frac{1}{c} \frac{\partial \phi(\vec{r}, \Omega)}{\partial t} + \hat{\Omega} \cdot \nabla \phi(\vec{r}, \Omega) + [\mu_a(\vec{r}) + \mu_s(\vec{r})] \phi(\vec{r}, \Omega) $$

$$ = \mu_a(\vec{r}) \frac{4\pi}{\alpha} f(\vec{r} \rightarrow \hat{\Omega}) \phi(\vec{r}, \hat{\Omega}) + s(\vec{r}, \hat{\Omega}) $$

where $\phi(\vec{r}, \hat{\Omega})$ is the local angular flux of photons at position $\vec{r}$, angle $\hat{\Omega}$ and time $t$ in a scattering medium. The absorption coefficient $\mu_a(\vec{r})$ describes photon absorption at position $\vec{r}$, and the scattering coefficient $\mu_s(\vec{r})$ describes photon scattering at position $\vec{r}$. The term $f(\Omega' \rightarrow \hat{\Omega})$ is the scattering phase function, which describes the probability of a photon scattered from direction $\Omega'$ into direction $\hat{\Omega}$. Term $S(\vec{r}, \hat{\Omega})$ is a source term for photons at position $\vec{r}$ and angle $\hat{\Omega}$. Equation (5) can be solved numerically or approximated analytically to determine the position- and angle-dependent flux of photons in a medium described by an arbitrary absorption, scattering, and phase function distribution.

Approximate analytical models include the following approximations. The simplest analytical model is the Beer–Lambert law, which assumes that the incident light on the medium attenuates exponentially in the direction of propagation within that medium. This is valid for a medium that does not scatter light, but is sufficiently absorbing that it can no longer be diluted, which is generally not true for tissues. The Kubelka–Munk approximation describes the time-independent, diffuse reflectance and transmittance for light incident on a tissue slab in terms of its spatially uniform absorption and isotropic scattering coefficients. The radiative transport equation also can be solved using the adding–doubling method for appropriate boundary conditions, and its solution can be compared with measurements of time-independent, diffusely reflected and transmitted light to estimate the absorption and scattering, as well as the anisotropy factors. Models based on Kubelka–Munk and the adding–doubling method are appropriate for the determination of tissue absorption and scattering coefficients in a wavelength region in which neither absorption nor scattering in tissue is dominant (UV/VIS spectral regions).

Within the diffusion approximation, which is valid far from sources and when the scattering coefficient is several orders of magnitude greater than the absorption coefficient, the spatial and temporal distribution of the diffusely reflected or transmitted light from tissue is related to the absorption and scattering coefficients and anisotropy factor. Diffusion theory is valid for cases where the absorption is low and scattering is high in tissues, such that the light is multiply scattered and travels through various optical path lengths before being detected (as in the NIR spectral region). When the probability of absorption in tissue becomes significant (as in the UV/VIS spectral regions), re-emitted light is minimally or moderately scattered and diffusion theory is no longer valid.

Numerical solutions to the transport equation include the method of discrete ordinates and the Monte-Carlo technique. These techniques can be used to model light transport in tissue over the entire UV/VIS/NIR spectral regions. The Monte-Carlo technique, which has been the
more popular of these numerical models, tracks individual photon trajectories, which are computer-simulated to calculate absorption and scattering coefficients (inverse calculation) or space irradiance distributions (forward calculation) for any tissue, tissue geometry and wavelength region. However, because tens of millions of photon trajectories must be tracked for statistical simulation of light transport in tissue, computations are time intensive.

The aforementioned numerical techniques can be used to compute the absorption and scattering coefficients and anisotropy parameter from measurements of diffusely reflected and transmitted light from tissue. Additionally, if the optical properties are known at the specific excitation and emission wavelengths and the fluorophore(s) quantum yield and distributions are provided, fluorescence excitation, emission and escape from the different depths within the tissue can be computed. Hence, these numerical techniques can be used to compute numerically the transfer function in Equation (4).

3.4 Turbid Tissue-simulating Phantoms for Fluorescence Spectroscopy of Tissue

In order to evaluate the effect of absorption and scattering and the illumination and collection geometry experimentally on fluorescence measurements from tissue, it is useful to employ tissue phantoms that simulate the optical properties and fluorescent properties of these biological media.

Durkin et al. developed a liquid tissue phantom that simulates the optical and fluorescence properties of tissues over the range 350–650 nm, with absorption coefficients in the range 25–5 cm$^{-1}$, scattering coefficients, in the range 400–200 cm$^{-1}$ and fluorophores in the micromolar concentration range. Phantom fluorophores included FAD and rhodamine B. Absorption was controlled by adjusting the hemoglobin concentration. Polystyrene spheres, which have a smoothly varying scattering coefficient as a function of wavelength, were used as the scatterers. Sample inhomogeneities were simulated by preparing the phantom in a gelatin substrate. These phantoms could be made dilute, absorbing and/or turbid.

Wagnieres et al. also developed tissue phantoms that have the optical characteristics of biological tissues in the wavelength range 400–650 nm, with absorption coefficients in the range 21–0.7 cm$^{-1}$ and scattering coefficients in the range 680–220 cm$^{-1}$. The phantoms are made up of agarose dissolved in water to provide a transparent matrix, which is then loaded with silicon dioxide, Intralipid, ink, blood, azide, penicillin, bovine serum and fluorophores. The silicon dioxide and Intralipid particles are responsible for scattering, whereas the ink and blood are absorbers. The penicillin and azide are used to ensure conservation of the phantoms at 4 °C. The serum, and fluorophores such as Coumarin 30, produce fluorescence. The mechanical properties of these gelatinous phantoms render them easily moldable so that complex structures and shapes simulating layered or other inhomogeneous structures containing various amounts of absorber, scatterer and fluorophore can be developed.

4 INSTRUMENTATION

In order to perform quantitative fluorescence spectroscopy of tissue, the fluorescence emission spectra and the reflectance and/or the diffuse reflectance and transmittance need to be measured. The latter are needed if tissue optical properties are to be quantified. However, because intact issues are semi-infinite media, only fluorescence emission and reflectance spectra are measured from these biological systems.

A schematic of the basic components of an instrument used for fluorescence and/or reflectance spectroscopy of tissues is shown in Figure 9. It consists of a light source, a flexible, conduit that contains optical fibers for the illumination and collection of light, a dispersing element that separates the emitted light into its respective wavelengths, and a detector that measures the intensity at these wavelength(s). In this scenario, fluorescence emission and reflectance are measured in a re-emission geometry in which the illumination and collection are performed on the same surface of the tissue. The various types of instruments employed for these measurements essentially have the same basic components.

4.1 Light Sources

Lasers, which have a very narrow spectral output, are generally used as monochromatic excitation light sources for fluorescence spectroscopy, whereas lamps with a broad spectral output are more appropriate for...
BIOMEDICAL SPECTROSCOPY

reflectance spectroscopy. Lamps also can be used as quasi-monochromatic excitation light sources for fluorescence spectroscopy when coupled with a monochromator or narrow-bandpass filter (see section 4.3). The need for portable light sources for clinical applications has limited the use of monochromatic light sources in the UV/VIS spectral range to the nitrogen pumped-dye laser (fundamental wavelength is 337 nm) and the helium–cadmium laser (wavelengths are 325 and 442 nm). Additionally, a dye module coupled to the nitrogen laser enables the generation of VIS laser wavelengths through the use of appropriate chemical dyes in a resonant cavity. Other lasers that have been used for fluorescence spectroscopy include the argon ion (UV and blue), helium neon (red) and krypton ion (blue) lasers. Portable polychromatic sources include the mercury and xenon arc lamps. The primary criteria for the selection of light sources, in addition to portability, are output power, bandwidth, wavelength tunability, coupling efficiency (into optical fibers) and the need for pulsed versus continuous wave light sources.

The power from a portable nitrogen laser at 337 nm is \(300 \mu\text{J} \) per pulse. At a maximal repetition rate of 30 Hz its average power is \(\sim 9 \text{mW} \). Because the nominal conversion efficiency of dyes used to generate VIS wavelengths is approximately 10\%, the average power in this case would be \(\sim 1 \text{mW} \). The output power from the helium–cadmium laser ranges from 5 mW at 325 nm to 15 mW at 442 nm. Commercially available mercury and xenon arc lamps can be operated over a range of 50–1000 W. Owing to excess generation of heat in the IR, clinical applications employing these lamps have been restricted to the use of power supplies between 75 and 300 W, with a liquid filter for IR rejection. Note that the output powers available for tissue illumination are significantly lower than the output powers specified, due to coupling losses from the light source into the optical fibers and/or coupling optics.

Although the UV/VIS lasers afford a very narrow spectral band (1–2 nm), the bandwidth of illumination from a lamp is determined by the use of narrow-bandpass filters or a monochromator (see section 4.3), which is used for wavelength dispersion. In general a 10–20 nm bandpass for the light source is sufficient, because tissue fluorescence emission spectra are broad with a 40–60 nm full width at half-maximum (fwhm).

The advantages and disadvantages of using a lamp versus a laser for fluorescence spectroscopy should be considered. An advantage of using a mercury or xenon lamp over a laser is that it provides wavelength tunability over the UV/VIS spectral range, as shown in Figure 10.\(^{68}\) However, the disadvantage of using a lamp over a laser is that the coupling efficiency into optical fibers can be reduced by a factor of 20 compared to laser coupling.\(^{69}\) due to the relatively large focal spot diameter of arc lamps. Finally, lasers with very short pulse duration (of the order of nanoseconds) are necessary when the tissue needs to be illuminated with pulsed excitation light for gated detection (which provides effective rejection of ambient light during fluorescence measurements) and for fluorescence lifetime measurements.

4.2 Illumination and Collection of Light

With respect to illumination and collection of light from tissue, two different approaches may be considered: the contact approach, where fiber-optic probes are placed directly in contact with the tissue surface; and the noncontact approach, where a series of lenses are used to project the light onto the tissue surface and collect it in a similar manner. With the contact approach, variable pressure on the tissue may distort the signal. However, with the noncontact approach the signal strength will vary
with the source–tissue and tissue–detector distances. In general, the contact approach is used for steady-state and time-resolved fluorescence and reflectance spectroscopy from small tissue volumes, whereas the noncontact approach is more suited for imaging larger tissue areas.

For the fiber-optic-based approach, typically multimode, step-index fibers with a core diameter ranging from 100 µm to 1 mm and f numbers (see section 4.3) of 2–4 are used for UV/VIS, fluorescence and reflectance spectroscopy. Fused-silica optical fibers are used for UV-excited fluorescence spectroscopy because standard silica fibers generate fluorescence with UV excitation. The fluorescence emission spectra of turbid media such as tissue are extremely dependent on the illumination and collection geometry due to the interaction of absorption and fluorescence. As shown elsewhere, design of a fiber-optic probe configuration that reduces the distortion of the fluorescence emission spectrum due to tissue absorption consists of a geometry in which the tissue fluorescence is collected only from that surface directly illuminated by the excitation light. Richards-Kortum et al. first designed optical fiber probes with illumination and collection geometries that enable maximal overlap between excitation and emission areas on the tissue surface.

In general, reflectance spectroscopy refers to the detection of both the diffuse (multiply scattered) and specular (surface) components of the reflectance. When measuring the diffuse reflectance from tissues, the photons that are detected generally undergo multiple scattering events and the photon path lengths are much greater than the geometric separation between the source and detector. Consequently, through this measurement, the probe is able to sample features in the tissue volume. Because specular reflection is due to refractive index mismatch and is generally a 2% reflection of the incident light in the case of an air/tissue interface, it needs to be minimized in attempting to make diffuse reflectance measurements. In order to minimize specular reflection, geometries have been employed in which the source and detector fiber are placed adjacent to each other, so that the specularly reflected light is not coupled to the detector fiber. However, this geometry precludes the ability to collect diffuse reflectance from the same site that is illuminated. This presents two problems: there is attenuation of the signal; and if fluorescence measurements are made from the same site of illumination there will be a lack of congruence between the fluorescence and reflectance measurements. One way to minimize specular reflection in a case where the diffuse reflectance is collected from the same site that is illuminated is to have the distal tip of the collection fiber angled at 17° from the direction normal to the optical fiber axis, such that the specular reflection is not coupled but the diffuse reflectance is.

4.3 Monochromators and Spectrographs

Light can be dispersed spectrally using a monochromator or a spectrograph, which are both dispersing components. A monochromator presents one wavelength or bandpass at a time of the input light from its exit slit, whereas a spectrograph presents a range of wavelengths simultaneously at the exit focal plane. Monochromators can be used as filters in conjunction with arc lamps to produce a series of monochromatic outputs for sample illumination (if only a few wavelengths are needed, narrow-bandpass filters may be more appropriate) or can be used to disperse the emitted light into its respective wavelengths, each of which can be detected serially using a single-channel detector. Spectrographs can be used to disperse the emitted light into its respective wavelengths simultaneously for multichannel detection.

The key components of a monochromator/spectrograph are: an entrance slit; a collimating lens; a grating (dispersing unit) for wavelength selection; a focusing lens; and an exit slit (see Figure 11). Grooves in diffraction gratings are manufactured either classically with the use of a ruling engine (ruled gratings) or holographically with the use of interference fringes generated at the intersection of two laser beams (holographic gratings). Groove densities generally range from 50 to 3600 grooves mm⁻¹. Holographic gratings have a higher groove density than ruled gratings.

Parameters that are relevant to the selection of a monochromator/spectrograph are the reciprocal linear dispersion (mm nm⁻¹), transmission efficiency, f number and stray light rejection. The reciprocal linear dispersion (which is inversely related to the grating groove density, diffraction order and focal length of the focusing element), when multiplied by the entrance slit width, provides the spectral resolution. For fluorescence and

![Figure 11](image-url)
reflectance spectroscopy, generally a spectral resolution of 10 nm is sufficient because these spectra are broad band and hence lack structure within this bandpass. Transmission efficiencies of both holographic and ruled gratings are comparable (~40%) in the VIS spectral region, and the efficiency of a particular grating is maximal at the wavelength at which it is blazed. Collection efficiency is reflected by the f number, which is defined as the ratio of the focal length and diameter of the collimating element. Lower f numbers are usually associated with a higher light gathering power or throughput. However, higher f-number spectrographs with longer focal-length-collimating elements are generally used to project a wide, flat field ideal for multichannel imaging detectors. For the applications indicated here, generally f numbers that match those of standard optical fibers (~2–4) are selected in order to maximize coupling efficiency. Stray light in monochromators/spectrographs is due to diffusion of light by optical components, including gratings and mirrors. Stray light is reduced by using holographic gratings, which usually give an order of magnitude better stray light rejection than classically ruled gratings. Typical stray light rejection for UV/VIS, fluorescence and reflectance spectroscopy should be specified to five orders of magnitude lower than the signal. Otherwise, long-pass filters with an optical density of at least 5.0 at the wavelength of excitation have to be employed to block the excitation light from the detector.

4.4 Detectors

The important considerations in choosing a detector are the type of measurements being made, i.e. single wavelength versus multiwavelength and single pixel (small region of the tissue surface) versus multipixel (relatively larger tissue area). Fluorescence and reflectance measurements from single pixels can be made either using a single-channel or multichannel detector. If measurements at only one or several wavelengths are being made, a single-channel photoemissive tube – called a photomultiplier tube (PMT) – or a semiconductor-based avalanche photodiode (APD) with a bandpass filter can be used. For fluorescence or reflectance spectroscopy, a spectrograph coupled to a multichannel, linear photodiode array (PDA) is appropriate. Fluorescence and reflectance spectroscopy also can be performed using a monochromator coupled to a PMT, albeit this substantially increases the measurement time. In the case of measurements from multiple pixels on the tissue surface, a two-dimensional charge-coupled device (CCD) camera may be employed. In order to reduce or eliminate the detection of ambient light during fluorescence spectroscopy, a detector with an intensifier for fast gating (several nanoseconds) must be used in conjunction with a pulsed excitation light source.

With respect to general detector performance, other considerations include quantum efficiency and sources of noise. For the detector, the quantum efficiency is defined as the ratio of induced current to the induced flux (often measured in electrons per photon). The quantum efficiency depends on the wavelength of light used, the material type and shape and other physical parameters. Figure 12 displays the quantum efficiency of a PMT and PDA/CCD.\(^{(70)}\)

The noise components that we must consider when detecting light are as follows:

- Shot noise, which is due to random statistical fluctuations of the incident light. Shot noise increases with the square root of the signal.
- Dark signal, which comes from the random generation of electrons. Dark signal is temperature dependent and thus can be reduced by cooling the detector.
- Readout noise, which comes from the electronic process of reading the signal from the detector.

The dark flux for a PMT lies in the range 2–50 e\(^{-}\) s\(^{-1}\). The readout noise is essentially zero because the pulse-height discrimination effectively avoids quantization noise. Although the un-intensified PDAs have been applied where the light levels are high, as in the case of reflectance spectroscopy, intensified PDAs are more suitable for fluorescence spectroscopy in which light levels are several orders of magnitude lower. In an intensified PDA, a microchannel plate intensifier is used to amplify the photoelectrons by a factor of 3000. Typical dark (at \(-20^\circ C\)) and readout noises are 40 counts s\(^{-1}\) and 3 e\(^{-}\), respectively (manufacturer specification is 1 count per e\(^{-}\)). The dark current of the CCD cameras range from 12 e\(^{-}\) pixel\(^{-1}\) s\(^{-1}\) at \(-40^\circ C\) to 0 e\(^{-}\) pixel\(^{-1}\) s\(^{-1}\) when cooled to \(-110^\circ C\). Their readout noise ranges from 12 to 4 e\(^{-}\).

![Figure 12 Quantum efficiency of a PMT and PDA/CCD.](image)
4.5 Signal-to-noise Ratio Analysis of an Instrument Used for Fluorescence Spectroscopy of Tissue

To establish the performance of an instrument for fluorescence spectroscopy of tissue (fluorescence rather than reflectance measurements are limiting in signal to noise), Zangaro et al. did a signal-to-noise ratio analysis using typical components. They used a nitrogen pumped-dye laser coupled to a fiber-optic probe for illumination and collection, and a spectrograph coupled to an intensified PDA for detection. Their calculation is as follows. The output pulse energy of the nitrogen laser is \( \sim 300 \mu J \). If the dye module is used, the nominal conversion efficiency is around 10 %, but with surface reflection losses it becomes 25 \( \mu J \) per pulse. They calculated losses of 40 % in coupling this light to a 200-\( \mu m \) core fiber, in output noise for the PDA is 3000 electrons. Using these loss parameters is approximately 130. Trujillo et al. have also done a systematic evaluation of the signal-to-noise ratio of a typical instrument used for fluorescence spectroscopy of tissue. In addition, they have developed an analytical expression to calculate the fluorescence efficiency of tissue and quantum efficiency using the same apparatus.

4.6 Calculation of Tissue Fluorescence Efficiency

In order to calculate the expected signal-to-noise ratio of a fluorimeter, two quantities are required: the throughput and inherent noise of the fluorimeter; and the fluorescence efficiency of the tissue volume probed. The throughput and inherent noise of the fluorimeter is a function of the delivery of the excitation light to the tissue surface, the collection of the fluorescence from the tissue surface, and finally conversion of the optical signal to an electronic signal. The calculation of these three quantities has been described in section 4.5. The fluorescence efficiency is the quantitative relationship between the excitation and emission energy. Trujillo et al. have developed an analytical expression to calculate the fluorescence efficiency of tissue from fluorescence emission spectra of tissues measured in vivo.

The fluorescence efficiency \( (FE) \) of a turbid sample is defined as the ratio of the total emitted photons to the excitation photons and is described as shown in Equation (7):

\[
FE = \frac{\int_0^\infty \int_0^\infty \int_0^\infty \mu_a(\lambda_x, z) \phi(\lambda_m, z) H_{out}(\lambda_m, z) \, dz \, d\lambda_m \, H_{in}(\lambda_x, z) \sum_k \mu_d(\lambda_x, z)}{\int_0^\infty \int_0^\infty \int_0^\infty \mu_a(\lambda_x, z) \phi(\lambda_m, z) H_{out}(\lambda_m, z) \, dz \, d\lambda_m \, H_{in}(\lambda_x, z) \sum_k \mu_d(\lambda_x, z) \Omega_t}
\]

where \( \lambda_x \) is the excitation wavelength, \( \lambda_m \) is the emission wavelength, \( z \) is the depth within the sample, \( \mu_a(\lambda_x, z) \) represents the absorption coefficient at the excitation wavelength of the fluorophore at depth \( z \), \( \phi(\lambda_m, z) \) is the fraction of the absorbed energy converted to fluorescence at the emission wavelength of the fluorophore at depth \( z \), and \( H_{in}(\lambda_x, z) \) and \( H_{out}(\lambda_m, z) \) represent the attenuation of the excitation and emission light, respectively, at depth \( z \). The fluorescence efficiency is independent of the power of the intensity at the excitation wavelength and the illumination/collection geometry. The fluorescence efficiency of an unknown turbid sample can be calculated from fluorescence measurements of the known sample and fluorescence measurements of an optically dilute homogeneous standard with a known absorption coefficient \( \mu_a \) and quantum efficiency using the same apparatus. Given the fluorescence emission spectrum of the turbid sample and that of a homogeneous standard with a known \( \mu_a \) and quantum efficiency, the fluorescence efficiency of the turbid sample can be expressed by Equation (8):

\[
FE_t(\lambda_x, \lambda_m) = \frac{\int_0^\infty P_t(\lambda_x, \lambda_m) \, d\lambda_m}{\int_0^\infty P_{std}(\lambda_x, \lambda_m) \, d\lambda_m} \times \frac{\int_0^\infty d\lambda_m H_{in-std}(\lambda_x, z) \mu_a \, H_{out-std}(\lambda_m, z) \Omega_t}{\int_0^\infty \mu_a \, H_{in-std}(\lambda_x, z) \mu_a \, H_{out-std}(\lambda_m, z) \Omega_t}
\]
where the subscript “t” corresponds to that of the turbid sample, the subscript “std” corresponds to that of the homogeneous standard, \( P_t \) is the total integrated fluorescence power of the turbid sample, \( P_{\text{std}} \) is the total integrated fluorescence power of the homogeneous standard (both of which can be measured), and \( \Omega_t \) and \( \Omega_{\text{std}} \) represent the collection efficiency of the turbid sample and homogeneous standard respectively. The first term in Equation (8) can be calculated from the ratio of the total integrated fluorescence power of the turbid sample and the homogeneous standard. The second term requires knowledge of the optical properties as well as the collection geometry of the homogeneous standard. The authors used a rhodamine solution in a cuvette as the homogeneous standard in these calculations. Because the rhodamine standard used is an optically dilute homogeneous solution, and the numerical aperture of the excitation and collection is small (0.22), the attenuation of the excitation light and fluorescent light in the rhodamine standard can be described with the simple Beer–Lambert Law.\(^{(2)}\) Hence, the wavelength-dependent \( \mu_a \) can be calculated simply from the measured rhodamine absorbance. The quantum efficiency of rhodamine is unity.\(^{(72)}\) The double integral in Equation (8) can be evaluated by using the measured values of \( \mu_a(\lambda_x) \) and \( \Phi(\lambda_m) \) of the homogeneous standard. If \( \Phi(\lambda_m) \) is not known but the quantum efficiency is, then an alternative method can be used to calculate the fluorescence efficiency, which requires changing \( \Phi(\lambda_m) \) into the quantum efficiency \( Q.E \) (defined by Equation 9):

\[
Q.E = \frac{\int_{\lambda_x}^{\infty} \Phi(\lambda_m) d\lambda_m}{\int_{\lambda_x}^{\infty} \mu_a(\lambda_x) d\lambda_x}
\]

Figure 13 displays the average fluorescence efficiency calculated from the fluorescence emission spectra of a total of 374 human cervical tissues at three excitation wavelengths in vivo. In Figure 13, the average fluorescence efficiency values are plotted for normal squamous tissue, normal columnar tissues, low-grade squamous intra-epithelial lesions (SIL) and high-grade SIL at excitation wavelengths 337, 380 and 460 nm. Standard deviations are shown as error bars. For squamous cervical tissues, the fluorescence efficiency decreases as tissue progresses from a nondiseased normal squamous to a diseased state (low-grade and high-grade SIL). Furthermore, as the excitation wavelength increases, the fluorescence efficiency decreases. The fluorescence efficiencies shown here are instrument independent and can be used to determine the signal-to-noise ratio needed to measure fluorescence emission spectra from tissues for different instrument configurations and excitation–emission collection geometries.

5 CLINICAL APPLICATIONS

Currently, one of the most widely explored applications of fluorescence spectroscopy is the detection of endoscopically invisible, early neoplastic growth in epithelial tissue sites. Early neoplastic growth refers to precancerous changes such as dysplasia and carcinoma in situ, which precede invasive cancer or carcinoma. Currently, there are no effective diagnostic techniques for these early tissue transformations. Fluorescence spectroscopy is ideally suited for this application because of its ability to examine tissue surfaces rather than tissue volumes, and its adaptability to an endoscopic device. If fluorescence spectroscopy can be applied successfully as a diagnostic technique in this clinical context, it may increase the potential for curative treatment and thus reduce complications. In addition to the potential for improved patient outcome, the fast and noninvasive nature of this diagnostic technique may also reduce health care costs.

Steady-state fluorescence measurements from small tissue regions (less than a few millimeters in diameter) as well as steady-state fluorescence imaging of relatively large tissue fields (a few centimeters in diameter) have been performed.\(^{(11,12)}\) To a much lesser extent, time-resolved fluorescence measurements are being explored currently.\(^{(11,12)}\) Furthermore, sources of both intrinsic (endogenous fluorophores) and extrinsic (exogenous fluorophores) fluorescence have been considered.\(^{(11,12)}\) The advantage of using exogenous fluorophores is that the photophysical and pharmacokinetic properties can

![Figure 13](image-url)
be selected and are known. Furthermore, exogenous fluorophores are more highly fluorescent than endogenous fluorophores. On the other hand, the disadvantage of using exogenous fluorophores is that issues relating to safety and toxicity of the drug being used have to be addressed. Furthermore, the selection of the optimal time delay after administration of the drug is nontrivial.

Several authors have reviewed the progress in this field over the last decade. Andersson-Engels et al.\textsuperscript{5,6} discussed the possibilities of using fluorescence spectroscopy for tissue diagnosis. The tissue types discussed were malignant tumors and atherosclerotic lesions. Studies of endogenous fluorescence as well as exogenous fluorescence with contrast agents were also presented. In a subsequent review, Andersson-Engels et al.\textsuperscript{7} reviewed the scientific, technical and practical issues related to the use of fluorescence spectroscopy for tissue diagnosis in clinical oncological applications. Papazoglou\textsuperscript{8} presented a review on the diagnosis of malignancies and atherosclerotic plaques using fluorescence spectroscopy. Special emphasis was given to problems that were raised during clinical trials and recent experimental studies, such as the identification of the fluorescent chemical species and the determination of the illumination/collection geometry for fluorescence spectroscopy of tissue. Bigio et al.\textsuperscript{9} reviewed fluorescence spectroscopy and elastic scattering spectroscopy of small regions of tissue, whereas Andersson-Engels et al.\textsuperscript{10} focused on fluorescence spectroscopy of relatively large tissue fields. Richards-Kortum et al.\textsuperscript{11} and Wagnieres et al.\textsuperscript{12} have written more comprehensive reviews. The former review focuses on the quantitative aspects of fluorescence spectroscopy. Specifically, this review describes optical interactions pursued for biomedical applications, provides a descriptive framework for light interactions in tissue and, finally, reviews the important endogenous and exogenous molecules and how they are exploited for tissue diagnosis. The latter review, which focuses more on clinical aspects, presents a critical status report on the diagnosis of neoplastic tissues in vivo using fluorescence spectroscopy.

5.1 Neoplasia

5.1.1 Endogenous Fluorescence

The phenomenon of fluorescence was first observed by Stokes.\textsuperscript{73} Much later, Stuble recognized the diagnostic potential of tissue fluorescence.\textsuperscript{74} Policard\textsuperscript{47} observed red fluorescence when examining necrotic tumors under illumination with UV and VIS light. Ronchese\textsuperscript{48} demonstrated in 1954 that ulceration is essential for the production of red fluorescence in human cutaneous, squamous cell carcinoma. The observed fluorescence was attributed to endogenous porphyrins in the tissue. Ghadially et al.\textsuperscript{39,49–51} also reported that ulcerated squamous carcinomas exhibit a red fluorescence when exposed to UV light. They concluded that this red fluorescence may be due in part to the action of bacteria on a protoporphyrin precursor. In 1965, Lycette et al.\textsuperscript{75} suggested that fluorescence spectroscopy could be used to discriminate between normal tissues and malignant tumors. Fluorescence emission spectra were recorded from excised normal tissue and malignant tumors of the esophagus, stomach, breast and thyroid at 330 nm excitation. All tissues fluoresced in the range 360–600 nm. It was found that the fluorescence intensities of malignant tumors were less than that of normal tissue from the same patient. Subsequently, the groups of Profio,\textsuperscript{76,77} Alfano,\textsuperscript{78} Lohmann\textsuperscript{79} and Yang\textsuperscript{80} did pioneering studies on in vitro and in vivo fluorescence spectroscopy of neoplastic and nonneoplastic animal and human tissues.

Fluorescence spectroscopy has been used to evaluate neoplastic and nonneoplastic tissues in vitro and in vivo. Generally, the results of in vitro studies have been used to guide the design of experimental parameters for in vivo studies.\textsuperscript{81} However, in vitro studies can introduce significant artifacts due to hemoglobin reabsorption and oxidation of certain fluorophores,\textsuperscript{82} questioning the relevance of in vitro studies to in vivo studies. Richards-Kortum et al.\textsuperscript{11} review in vitro and in vivo studies on fluorescence spectroscopy of neoplasia and in vitro studies on fluorescence spectroscopy of atherosclerosis. This review covers only in vivo studies, in order to demonstrate the diagnostic potential of fluorescence spectroscopy in clinical applications.

UV/VIS fluorescence spectroscopy can be developed and employed to differentiate diseased from nondiseased tissues in vivo. The altered biochemical and morphological state that occurs as tissue progresses from a nondiseased to a diseased state is reflected in the spectral characteristics of the measured fluorescence. This spectral information can be compared to tissue histology – the current gold standard – which indicates the absence or presence and grade of disease. Mathematical algorithms then can be developed and optimized to classify tissues into their respective histological category based on their spectral features. These mathematical algorithms can be implemented in software, thereby potentially enabling fast, noninvasive, automated screening and diagnosis in a clinical setting. Although the signal-to-noise ratio of fluorescence spectroscopy is several orders of magnitude lower than that associated with absorption spectroscopy over the same wavelength range, this technique affords higher sensitivity and specificity for biochemical characterization.

Table 2\textsuperscript{83–100} summarizes the key aspects of a representative set of clinical applications of fluorescence spectroscopy (the most recent investigation per group and investigations from groups who reported the performance

a Acronyms: I = intensity; τ = decay time; MVLR = multivariate linear regression; PCA = principal component analysis; λx = excitation wavelength; λm = emission wavelength; ND = nondiseased; D = diseased; SE = sensitivity; SP = specificity; N/A = not applicable.
b Sensitivity and specificity were evaluated prospectively.
c Sensitivity and specificity were evaluated for a combination of fluorescence and conventional endoscopic techniques.
d Sensitivity and specificity were calculated for the discrimination between cancers and noncancers (other investigations calculated the sensitivity and specificity for discriminating precancers and cancers from normal tissues).

do Not applicable.

of their technique). In these applications, fluorescence spectroscopy in the UV/VIS spectral regions was used for the detection of neoplastic tissues in vivo. In particular, Table 2 provides the organ sites studied, the excitation wavelength(s) used, the type of measurements that were made, the dimensionally reduced spectral variables and the corresponding classification scheme used in the mathematical algorithm, the sample size for the diseased and nondiseased populations and the corresponding sensitivity and specificity. Note that in all these clinical applications only the endogenous fluorescence, absorption and scattering properties of the tissue were exploited.

The neoplastic tissues that were evaluated spectroscopically are from the colon,83–87 cervix,88,89 bronchus,90 bladder,91,92 brain,101 (preliminary studies only), esophagus,93 oral cavity,94,95 head and neck,96,97 larynx,98,99 skin,100 bile duct102 (preliminary studies only), stomach103 (in vitro studies only) and breast tissues104–107 (in vitro studies only). The excitation wavelengths that were selected correspond to those used to excite fluorophores in the UV/VIS spectral regions (see Table 1). Most groups measured fluorescence emission spectra from tissue sites that are 1–2 mm in diameter. Only a few groups measured fluorescence images from tissue regions that are a few centimeters in diameter, and only one group measured the transient fluorescence decay from colon tissues in vivo.

There are generally two steps involved in the development of a mathematical algorithm that is based on fluorescence spectroscopy. The first part is to reduce dimensionally the measured spectral variables, and the second step is to develop a classification scheme for the discrimination of these useful spectral parameters into relevant histological/histopathological categories. The development of current mathematical algorithms based on fluorescence spectroscopy can be classified broadly into three categories: algorithms based on qualitatively selected spectral variables (fluorescence intensities at several emission wavelengths); algorithms based on statistically selected spectral parameters (a more robust use of all the measured spectral information); and algorithms based on parameters that reflect the biochemical and/or morphological features of the tissue. Classification schemes have been primarily based on a binary discrimination or a probability-based classification scheme.
Mostly, algorithms have been based on qualitatively or statistically selected spectral variables with binary classification schemes as indicated in Table 2.

The sensitivity is defined as the fraction of diseased samples correctly classified, and the specificity is defined as the fraction of nondiseased tissues correctly classified. In several clinical studies, the sensitivity and specificity were evaluated prospectively rather than retrospectively to obtain an unbiased estimate of the performance of this technique.\(^\text{(85,88,89)}\) In some cases the sensitivity and specificity were evaluated for a combination of fluorescence spectroscopy and conventional endoscopy.\(^\text{(90,98,99)}\) Finally, in the case of the bladder, head and neck and larynx, the sensitivity and specificity are reported for the discrimination between cancers and noncancers.\(^\text{(91,92,96–99)}\) In other clinical applications, the sensitivity and specificity are reported for the discrimination of precancers and cancers from normal tissues. In the majority of clinical studies performed the sensitivity and specificity are greater than 80\%, reflecting the high classification accuracy of fluorescence spectroscopy for the detection of neoplastic tissues in vivo. The sensitivity and specificity reported here are similar or superior to current clinical modalities that are used routinely.

### 5.1.2 Exogenous Fluorescence

There are a number of groups that have explored the diagnostic potential of fluorescence spectroscopy of exogenous fluorophores (particularly photosensitizing agents developed for PDT) in tissues in vivo.\(^\text{(108)}\) Auler et al.\(^\text{(108)}\) and Figgie\(^\text{(109)}\) first observed red fluorescence from animal tumors after administration of exogenous porphyrins. The first use of fluorescein to improve the detection and identification of brain tumors in vivo was reported by Moore et al.\(^\text{(110)}\) The accumulation of hematoporphyrin in various types of cancers was discovered and exploited during the 1950s.\(^\text{(111–113)}\) HpDs were evaluated subsequently for localization in cancers of various organs, including the esophagus, tracheobronchial tree and cervix,\(^\text{(114–120)}\) and for characterizing suspicious head and neck lesions.\(^\text{(121)}\) The first cystoscopic observations of HpD fluorescence in urinary bladder tumors were reported by Kelly et al.\(^\text{(122)}\) These and other initial clinical and animal model studies of HpD-mediated PDT led to fluorescence diagnostic applications by many other groups using this exogenous fluorophore. Subsequently, Kreigmair et al.\(^\text{(123)}\) proposed the use of 5-ALA-induced PpIX fluorescence for the detection of bladder neoplasms.

Photosensitizing agents, particularly HpD and 5-ALA, have been used as contrast agents for fluorescence spectroscopy of neoplastic tissues in a wide variety of tissue sites, including the skin, bladder, bronchus, colon, esophagus, head and neck, and breast.\(^\text{(122)}\) However, because most of these exogenous fluorophores rely on the differences in the vasculature between diseased tissues (which generally exhibit leaky vessels) relative to their nondiseased counterparts, it remains to be seen whether the characteristics that determine localization of the exogenous fluorophore in cancers are also present in precancerous tissues.

### 5.2 Atherosclerosis

Edholm et al.\(^\text{(124)}\) suggested that quantitative optical techniques could be used to improve the detection of atherosclerosis in vivo; they measured the reflectance of the aorta at 500 and 550 nm in 15 patients undergoing aortography. Kitrell et al.\(^\text{(125)}\) demonstrated that fluorescence spectroscopy could be used to discriminate between normal aorta and fibrous plaque, and suggested that optical diagnosis (using low-power illumination) and therapy (using high-power illumination) of atherosclerosis could be combined in a single fiber-optic device. Subsequently, a number of groups investigated the utility of fluorescence spectroscopy for the diagnosis of atherosclerotic plaque, many with the goal of developing a guidance system for laser angiosurgery catheters.\(^\text{(8,11)}\)

The fluorescence emission spectra of normal artery tissue and atherosclerotic plaques have been measured over the entire range of UV/VIS excitation wavelengths.\(^\text{(11)}\) However, most of these investigational studies to demonstrate the diagnostic potential of fluorescence spectroscopy have been performed in vitro on excised tissues and hence have not addressed the problems of making these measurements in vivo on the intact artery wall.

### 6 CLINICAL INSTRUMENTS

In this section representative examples of instruments used in clinical applications of fluorescence spectroscopy are described. In particular, details of the instruments and typical data are presented to provide the reader with an understanding of the main characteristics of instruments for UV/VIS fluorescence spectroscopy.

#### 6.1 Single-pixel, Three-excitation-wavelength Fluorimeter

Although fluorescence emission spectra of normal tissue, dysplasia and invasive carcinoma have been measured previously from several organ sites in vivo at single excitation wavelengths (see Table 2), Ramanujam et al.\(^\text{(88)}\) were among the first to address the necessity to measure fluorescence emission spectra at several excitation
wavelengths in order to exploit more fully the tissue biochemistry and morphology. They developed a portable fluorimeter that can be used to measure fluorescence emission spectra from 1-mm-diameter human cervical tissue sites in vivo at three excitation wavelengths in the UV/VIS spectral regions. These wavelengths were selected primarily because they coincide with the absorption bands of biologically relevant fluorophores, namely the metabolic coenzymes and structural proteins and chromophores, which include oxygenated and deoxygenated hemoglobin. A schematic of the fluorimeter is shown in Figure 14.

Two nitrogen pumped-dye lasers (5 ns pulse duration, 30 Hz repetition rate) are used to provide illumination at three different excitation wavelengths: one laser generates light at 337 nm (fundamental) and has a dye module in a resonant cavity that can be used to generate light at 380 nm using the fluorescent dye BBQ. The dye module in the resonant cavity of the second laser is used to generate light at 460 nm, using the fluorescent dye Coumarin 460. Laser illumination at each excitation wavelength of 337, 380 and 460 nm is coupled to each of three excitation fibers in a fiber-optic probe. Note that two 10-nm bandpass filters – one centered at 380 nm and the other centered at 460 nm – are placed between the excitation fiber and the two dye modules, to prevent leakage from the fundamental at 337 nm.

The fiber-optic probe consists of a central fiber surrounded by a circular array of six fibers; all seven fibers have the same characteristics (0.22 numerical aperture, 200 µm core diameter, 245 µm diameter with cladding). Three fibers along the diameter of the distal end of the probe are used for excitation light delivery. The purpose of the remaining four fibers is to collect the emitted light from the tissue area directly illuminated by the excitation light. A quartz shield (3 mm in diameter and 2 mm thick) at the tip of the distal end of the probe, which is in direct tissue contact, provides a fixed distance between the fibers and the tissue surface so that the fluorescence intensities can be measured in calibrated units. A tissue area that is 1 mm in diameter is illuminated by each excitation delivery fiber. The average energies per pulse on the tissue surface at 337, 380 and 460 nm excitation were 15.2, 11.5 and 18 µJ mm⁻², respectively, in this case.

The proximal ends of the four emission collection fibers are arranged in a circular array and imaged at the 500-µm-wide entrance slit of an f 3.8 spectrograph equipped with a 300 grooves mm⁻¹ grating coupled to a 1024-intensified PDA controlled by a multichannel analyzer. The collection optics between the proximal end of the four fibers and the spectrograph are two, fused-silica, planoconvex lenses. Between these lenses is a filter wheel assembly containing long-pass filters with 50% transmission at 360, 400 and 475 nm, which are used to reject backscattered excitation light at 337, 380 and 460 nm excitation, respectively, from the detector. The nitrogen pumped-dye lasers are used for external triggering of a pulser, which serves to synchronize the 200-ns collection gate of the detector to the leading edge of the laser pulse. The use of gated detection in conjunction with pulsed excitation eliminates the effects of ambient light during fluorescence measurements. The total time required to record fluorescence emission spectra at all three excitation wavelengths from one tissue site was approximately 5 s. Spectra were collected in the VIS spectral region, with a resolution of 10 nm (fwhm).

Figure 14 Schematic of a three-excitation-wavelength system. (Reproduced by permission of the American Society for Photobiology, from Ramanujam et al.⁹⁸)
and a signal-to-noise ratio of 100:1 at the fluorescence maximum at each excitation wavelength. Data acquisition and storage are achieved using a computer.

All spectra were corrected for the nonuniform spectral response of the detection system using correction factors obtained by recording the spectrum of a National Institute of Standards and Technology (NIST) traceable, calibrated, tungsten ribbon filament lamp. Spectra from each cervical tissue site at each excitation wavelength were averaged to obtain a single spectrum per site. The average tissue spectra were then normalized to the average peak fluorescence intensity of the rhodamine 610 calibration standard for the corresponding excitation wavelength for that patient; absolute fluorescence intensities are reported in these calibrated units.

Figure 15 illustrates average fluorescence emission spectra per site acquired from cervical tissue sites at 337, 380 and 460 nm excitation from a typical patient. All fluorescence intensities are reported in the same set of calibrated units. Evaluation of the tissue spectra at 337 nm excitation indicates that the fluorescence intensity of the precancerous SIL is less than that of the corresponding normal squamous tissue and greater than that of the corresponding normal columnar tissue. Evaluation of the spectra at 380 nm excitation indicates that the fluorescence intensity of SIL is less than that of the corresponding normal squamous tissue, with the low-grade SIL exhibiting the weakest fluorescence intensity. Note that the fluorescence intensity of the normal columnar tissue is indistinguishable from that of the high-grade SIL. Finally, evaluation of spectra at 460 nm excitation indicates that the fluorescence intensity of SIL is less than that of the corresponding normal squamous tissue and greater than that of the corresponding normal columnar tissue. The spectra shown here demonstrate that it is possible to obtain fluorescence emission spectra from tissues in vivo at several excitation wavelengths, with a high signal-to-noise ratio and in a fast and noninvasive manner.

6.2 Single-pixel, Excitation–Emission Matrix System

It is apparent that fluorescence emission spectra at multiple excitation wavelengths spanning the UV/VIS spectral regions are needed to characterize properly the patho-physiologically relevant, endogenous fluorophores in tissue. Furthermore, reflectance measurements at these wavelengths are also needed to probe tissue absorption and scattering properties and enable deconvolution between the fluorescence, absorption and scattering. Zeng et al. developed an instrument to measure the fluorescence emission spectra and diffuse reflectance spectra from the human skin, simultaneously. However, this instrument was capable of measuring fluorescence emission spectra at only a single excitation wavelength of 380 nm.

Zangaro et al. integrated and improved upon the designs of Ramanujam et al. and Zeng et al. by constructing a fast EEM system that can measure fluorescence emission spectra at multiple excitation wavelengths and diffuse reflectance spectra from 1- to 2-mm-diameter tissue sites in vivo quickly and noninvasively. Preliminary considerations for the design of this system were as follows: rapid wavelength tunability and real-time data acquisition for fluorescence spectroscopy at multiple excitation wavelengths; the ability to measure diffuse reflectance in addition to fluorescence; gated detection of spectral measurement with minimal interference from ambient light; and capability for optical fiber delivery and collection. The system, which was designed with the aforementioned considerations in mind, is shown in Figure 16.

A nitrogen pumped-dye laser is used as the excitation light source. Delivery of light to tissue and collection of returned spectral information is accomplished by
Figure 16 EEM system designed to measure tissue fluorescence spectra at multiple excitation wavelengths and spectrally resolved broad band diffuse reflectance spectra in vivo. (Reproduced by permission of the Optical Society of America, from Zangaro et al.69/)

means of an optical fiber probe. A filter wheel placed in front of the spectrograph rejects backscattered excitation light. The fluorescence is dispersed in the spectrograph, detected by an intensified PDA, coupled to an optical multichannel analyzer and stored in a computer. The novel aspects of this system, which lends itself to multi-excitation fluorescence spectroscopy and diffuse reflectance spectroscopy of tissues in the UV/VIS spectral regions, are described below.

Dye cuvettes (with appropriate dyes) mounted on a rotating wheel that rapidly traverses a single resonant cavity are capable of generating multiple wavelengths. Also, a corresponding filter wheel placed in front of the spectrograph allows rejection of backscattered excitation light at each wavelength when synchronized with the dye wheel. Furthermore, a 10-µs pulsed xenon lamp is also incorporated such that diffuse reflectance measurements can be made over the UV/VIS spectral regions. Fiber-optic delivery and collection have been designed to provide for the remote operation of the system and for the measurement of fluorescence and diffuse reflectance directly from the tissue area that is illuminated, in order to remove the effects of the illumination/collection geometry.57,58 Furthermore, the fiber-optic probe was designed such that the diffuse reflectance and fluorescence can be made from the same tissue site. The acquisition time for both fluorescence and reflectance measurements is less than 1 s.

The performance of this system has been validated clinically by passing the fiber-optic probe through one of the accessory channels of a colonoscope and bringing it into flush contact with the tissue surface. Figure 17(a) displays fluorescence emission spectra at multiple excitation wavelengths and Figure 17(b) displays a diffuse reflectance spectrum from colon tissue. Figure 17(a) shows spectra measured at 10 excitation wavelengths in

Figure 17 (a) Fluorescence spectra at 10 excitation wavelengths and (b) diffuse reflectance spectrum over the UV/VIS spectral regions measured from a colon tissue site in vivo. (Reproduced by permission of the Optical Society of America, from Zangaro et al.69/)
the UV/VIS spectral regions. The spectra at the different excitation wavelengths appear to correspond with spectra of biologically relevant fluorophores, including collagen (337 nm excitation), reduced PN (360 nm excitation) and oxidized Fp (428 nm excitation). Note that the effects of hemoglobin absorption on the fluorescence emission spectra are observed at 337 nm excitation. Figure 17(b) shows the diffuse reflectance spectrum obtained from the same tissue site. The spectrum exhibits the absorption bands of hemoglobin at 420 nm (Soret band) and at 540 and 580 nm (α and β bands).

Zuluaga et al.\(^{129}\) have also developed a fast EEM system that measures fluorescence emission spectra at multiple excitation wavelengths and diffuse reflectance spectra rapidly (4 min total measurement time) and non-invasively from tissues in vivo. Specifically, the system measures the fluorescence EEM at 330–500 nm excitation and 380–700 nm emission. The diffuse reflectance spectra are measured at 380–950 nm. The primary difference between this system and that developed by Zangaro et al.\(^{69}\) is that it employs a white light source with a series of bandpass filters instead of a nitrogen pumped-dye laser for generating multiple excitation wavelengths for fluorescence spectroscopy. Furthermore, Zuluaga et al.\(^{129}\) present a method based on autocorrelation vectors to identify the excitation and emission wavelengths where the spectra of diseased and nondiseased tissues differ the most.

### 6.3 Fluorescence Imaging Systems

Several groups have developed endoscopic-compatible\(^{66,97,130–134}\) and nonendoscopic-based\(^{100,135,136}\) fluorescence imaging systems. The most notable is that originally developed by Palcic et al. for fluorescence bronchoscopy,\(^{130}\) which has now led to a commercial light-induced fluorescence endoscopy (LIFE) device (Xillix Technologies Corporation, Richmond, BC, Canada) that is used for fluorescence imaging of relatively large tissue fields (a few centimeters in diameter). The LIFE device consists of a white light source and a color CCD for the acquisition of white light images, a helium–cadmium laser and two filtered, high-sensitivity CCD cameras for the acquisition of green and red fluorescence images, an endoscope-compatible fiber-optic bundle and a computer with a monitor. The laser is used to provide excitation light at 442 nm. The fluorescence emitted is collected and coupled via an imaging, fiber-optic bundle to two filtered, image-intensified CCD cameras (one for the green wavelength band at 480–520 nm and one for the red wavelength band at 630 nm and longer). The fluorescence image is digitized using an imaging board in the computer. Using a mathematical transformation (a nonlinear discriminant function combination of the red and green intensity images), a pseudo-image of the observed tissue site is obtained and displayed on the monitor in real-time. Normal tissues appear green and neoplastic tissues appear brownish-red.

The LIFE device has been tested in a multicenter clinical trial to evaluate if fluorescence bronchoscopy, when used as an adjunct to white light bronchoscopy, can improve the bronchoscopist’s ability to locate areas suspicious of dysplasia for biopsy and histological examination as compared to white light bronchoscopy alone.\(^{90}\) The LIFE device also has been used successfully to evaluate neoplastic lesions in other organ sites, including the head and neck,\(^{96}\) larynx,\(^{98,99}\) bile duct,\(^{102}\) and gastrointestinal tract.\(^{137,138}\)

Recently, Zeng et al.\(^{134}\) elaborated on the fluorescence imaging system for the gastrointestinal tract. The device consists of a mercury arc lamp, two intensified CCD cameras, a fiber-optic endoscope and a computer-based console. The system is capable of working in three different modalities: conventional white light imaging mode; light-induced fluorescence imaging mode, based on fluorescence imaging of two wavelength bands in the red and green; and light-induced fluorescence and reflectance imaging mode, based on the combination of red and green fluorescence images and a red-NIR reflectance image.

### 7 METHODS OF ANALYSIS

Most screening and diagnostic algorithms developed from fluorescence spectroscopy of tissues incorporate qualitatively or statistically selected spectral variables, which are evaluated using a binary or probability-based classification scheme. For example, Panjehpour et al.\(^{93}\) have developed an algorithm that uses qualitatively selected, fluorescence intensities at several emission wavelengths in a binary classification scheme for the detection of Barrett’s esophagus in vivo. On the other hand, Ramanujam et al.\(^{88}\) have developed an algorithm that uses statistically selected spectral variables and probability-based classification for cervical precancer detection in vivo. This multivariate statistical algorithm employs PCA\(^{139}\) to reduce dimensionally the preprocessed tissue fluorescence emission spectra into orthogonal principal components with minimal information loss. Bayes theorem\(^{140}\) is then used to develop probability-based classification using the diagnostically relevant principal components. The advantage of using statistical rather than qualitative analysis of the tissue fluorescence emission spectra is that the entire spectral information content can be exploited. Furthermore, the benefit of using a probability, rather than a binary, classification scheme is that the likelihood of the classification being correct is also provided.
An example of an algorithm that uses biochemical and/or morphological features that are related to the tissue fluorescence emission spectra, coupled with a probability-based classification, is that developed by Richards-Kortum et al.\(^{141}\) This algorithm discriminates between normal coronary arteries and noncalcified and calcified atherosclerotic plaque in vitro. The contribution of the biochemical and/or morphological features is extracted from the tissue fluorescence emission spectra via an analytical model of tissue fluorescence, based on the exponential attenuation of light in an absorption-dominant medium. Bayes’ theorem is then used for probability classification.

The advantage of using a physically based model over a statistically based model is that the former method provides insight into the biochemical and morphological basis. However, there are notable advantages to using a statistical model such as PCA. Although it is a linear method of analysis, PCA can still be used to model effectively the nonlinear turbid tissue fluorescence. Because it is less restrictive, PCA can permit a better fit to the fluorescence emission spectra than simple physical models can, through the use of a linear combination of orthogonal principal components.\(^{142}\) In addition, the principal components are not correlated with each other and therefore can be used in a variety of classification algorithms that generally require un-correlated variables. Furthermore, each principal component can be correlated to the spectral variables of the original tissue fluorescence emission spectra, thus providing insight into the spectral features that contribute to the classification.

Most algorithms to date use qualitatively and, to a lesser extent, statistically selected variables with binary or probability-based classification schemes as indicated in Table 2. The development of a physically based model that uses biochemical and morphological features that are related to the measured tissue fluorescence emission spectra has been hampered by the fact that fluorescence spectroscopy of human tissue is greatly affected by the absorption and scattering of the excitation light and the emitted light, making interpretation of the measured spectral information challenging.\(^{53}\)

Given the high classification accuracy that can be achieved using statistically based algorithms,\(^{88}\) and the difficulties associated with the development of physically based algorithms,\(^{141}\) it is perhaps worthwhile considering the development of a hybrid algorithm that incorporates the key features of both. For example, the statistical model could be related to the physical model in order to realize the biochemical and/or morphological basis of the statistically selected spectral variables that are used for classification purposes.

Section 7.1 provides a detailed description of the algorithm developed by Ramanujam et al.,\(^{88}\) which uses statistically selected spectral parameters in conjunction with a probability based classification process. Section 7.2 discusses physically based models to analyze tissue fluorescence emission spectra and their potential to elucidate the biochemical and morphological features that contribute to the tissue fluorescence emission spectra. Section 7.3 presents various approaches to account for the illumination/collection geometry-related distortion of the tissue fluorescence emission spectra measured in vivo.

### 7.1 Statistically Based Model

Ramanujam et al.\(^{88}\) developed a formal analytical process for the development of screening and diagnostic algorithms for the detection of human cervical precancer or SIL in vivo. The formal analytical process is displayed in Figure 18, where the text in the dashed-line boxes represents the mathematical steps implemented on the spectral data, and the text in the solid-line boxes represents the output after each mathematical process. There are four primary steps involved in the multivariate statistical analysis of tissue fluorescence emission spectra. The first step is to preprocess spectral data to reduce interpatient and intrapatient variation within a tissue type; the preprocessed spectra are then dimensionally reduced to an informative set of principal components that describe most of the variance of the original spectral data set using PCA.\(^{139}\) Next, the principal components that contain diagnostically relevant information are selected using an unpaired, one-sided Student’s t-test, and finally a classification algorithm based on Bayes theorem\(^{140}\) is developed using these diagnostically relevant principal components.

In summary, three constituent algorithms were developed using multivariate statistical analysis: constituent algorithm 1 differentiates between SIL and normal squamous tissues; constituent algorithm 2 differentiates between SIL and normal columnar tissues; and algorithm 3 differentiates high-grade SIL from low-grade SIL. The three constituent algorithms were then combined to develop two composite algorithms: constituent algorithms 1 and 2 were combined to develop a composite screening algorithm that discriminates between SIL and non-SIL. All three constituent algorithms were then combined to develop a composite diagnostic algorithm that differentiates high-grade SIL from non-high grade SIL.

Inputs into the multivariate statistical algorithm included the preprocessed fluorescence spectra at all three excitation wavelengths (full-parameter) and fluorescence intensities at a reduced number of excitation–emission wavelength pairs (15 reduced parameters) selected from the component loadings calculated from PCA.\(^{139}\) The
algorithm was developed on a calibration set and tested on a prediction set of approximately equal numbers of samples in each tissue category. Table 3 compares the sensitivity and specificity of the composite screening and diagnostic algorithms with that of Pap smear screening and colposcopy in expert hands. Table 3 indicates that the composite screening algorithm has a similar specificity and a significantly improved sensitivity relative to Pap smear screening. A comparison of the composite screening algorithm to that of colposcopy in expert hands demonstrates a 10% decrease in sensitivity but a 20% improvement in specificity. The composite diagnostic algorithm and colposcopy in expert hands both discriminate high-grade SIL from non-high-grade SIL with a similar sensitivity and specificity. Finally, the sensitivity and specificity of the reduced-parameter algorithms that use an order of magnitude fewer variables is within 5% of the sensitivity and specificity reported for the full-parameter algorithms. This has important implications in using fluorescence spectroscopy to identify fluorescence intensities at a reduced number of optimal excitation–emission wavelength pairs for the implementation of fluorescence imaging.

### 7.2 Physically Based Models

Although it has been demonstrated that fluorescence spectroscopy can be used to differentiate diseased from nondiseased tissues with high sensitivity and specificity, the underlying biochemical and morphological basis for the spectral differences is poorly understood. This has been hampered by the fact that fluorescence spectroscopy of a turbid medium such as tissue is complicated by its absorption and scattering properties.

A fluorescence emission spectrum measured from tissue over the UV/VIS spectral region is primarily attributed to the superposition of the fluorescence of a variety of biological molecules that contain naturally occurring fluorophores. Fluorescence emission spectra...
measured from tissues also contain information about the absorbing and scattering properties of that medium. Quantification of the concentration and distribution of fluorophores within tissue in principle involves: deconvoluting the absorption and scattering properties of the tissue from the measured fluorescence emission spectrum; and quantifying the identity and distribution of the fluorophores that contribute to the deconvolved spectrum. The former step requires the development of a transfer function based on the measurements of tissue optical properties, whereas the latter step requires knowledge of the identity and distribution of the fluorophores within the tissue.

7.2.1 Transfer Function

Deconvolution of the absorption and scattering properties of the tissue from the measured fluorescence emission spectrum requires knowledge of the tissue optical properties, i.e., the absorption coefficient, the scattering coefficient and the anisotropy parameter. Analytical methods based on Kubelka–Munk theory, and the adding–doubling method have been developed to calculate tissue optical properties in the UV/VIS spectral range. However, these models require the measurement of diffuse transmittance and reflectance from tissues. Diffuse transmittance measurements cannot be made from tissues in vivo, thus limiting the number of parameters needed to determine tissue optical properties using these simple analytical techniques.

Several groups have developed simple analytical models based on measurements of fluorescence and diffuse reflectance only (no transmittance measurements are needed) to deconvolute absorption and scattering properties of the tissue from the measured fluorescence emission spectrum. These analytical techniques, although simplistic, do provide a first step towards quantifying the biochemical and morphological characteristics of tissue fluorescence emission spectra.

In particular, Gardner et al. have developed an analytical expression for recovering the intrinsic fluorescence coefficient (which is defined as the product of the fluorophore absorption coefficient and the fluorescence quantum yield) of a homogeneous turbid medium from a surface measurement of fluorescence and diffuse reflectance quantum yield (of the tissue) and quantifying the identity and distribution of the fluorophores that contribute to the deconvolved spectrum. The former step requires the development of a transfer function based on the measurements of tissue optical properties, whereas the latter step requires knowledge of the identity and distribution of the fluorophores within the tissue.

Using the analytical method developed by Gardner et al., one can recover the intrinsic fluorescence coefficient from the measured fluorescence using Equation (11):

$$\beta(\lambda_x, \lambda_m) = \frac{F(\lambda_x, \lambda_m)}{P_0(\lambda_x) [(\Delta\Omega/\pi) \cos \theta] D(\lambda_m) X_{1D}(\lambda_x, \lambda_m)}$$

where $F(\lambda_x, \lambda_m)$ is the measured fluorescence intensity, $P_0(\lambda_x)$ is the power of the incident light at the excitation wavelength, $D(\lambda_m)$ is the detector’s wavelength-dependent response function, $[(\Delta\Omega/\pi) \cos \theta]$ is the detector collection efficiency for a distant detector geometry, and a tissue surface with Lambertian intensity distribution, and $X_{1D}$ is the one-dimensional path length factor. The term $P_0(\lambda_x) [(\Delta\Omega/\pi) \cos \theta] D(\lambda_m)$ can be quantified by calibration of the fluorescence measurement for source and detector constants. Specifically, the fluorescence calibration can be performed with an optically dilute fluorophore solution with a predetermined intrinsic fluorescence coefficient. The path length factor $X_{1D}$ requires knowledge of the tissue optical properties at the excitation and emission wavelengths. This function is based upon the exponential attenuation of light away from the source, as are the Beer–Lambert and diffusion theories, with coefficients that are empirically developed from extensive Monte-Carlo simulations. Factor $X_{1D}$ can be calculated from noninvasive measurements of the diffuse reflectance ($R_d$) and effective penetration depth ($\delta$). Because two optical properties are needed, it is possible to make two, unique, diffuse reflectance measurements with two illumination–collection fiber distances in order to specify $R_d$ and $\delta$.

The recovery method presented successfully identifies the intrinsic fluorescence coefficient (both spectral line shape and intensity) of turbid tissue phantoms that incorporate various concentrations of fluorophore (rhodamine 6G), absorber (adult hemoglobin) and scatterer (polystyrene spheres) with absorption and scattering coefficients that coincide with the range found in soft tissues. The results are shown in Figure 19. Furthermore, fluorophore concentrations of the turbid tissue phantoms are predicted to within 15% of the true concentration (not shown).

Although this analytical model is simple and can recover the intrinsic fluorescence coefficient from turbid tissue phantom fluorescence emission spectra, there are several limitations associated with it. The optical properties of the medium need to be uniform. Furthermore, the size of the medium should be large enough such that only the surface boundary affects the distribution of light. Finally, the one-dimensional fluence rate expression is valid for collimated incident light with a beam diameter that is at least a factor of four larger than the penetration depth of the light.
Except for a constant scaling factor that potentially can be corrected for. Finally, using the PLS method, which was trained on a set of turbid tissue phantom spectra that have optical properties similar to those to be analyzed, fluorophore concentrations were predicted to within 5% of the true concentration. It should be noted that the success of the PLS method relies on a training set that reflects the chemical and optical properties of the tissue.

Figure 19 Summary of intrinsic fluorescence recovery from six turbid tissue phantoms: (a) measured uncorrected fluorescence spectra; (b) corrected fluorescence spectra, displayed as the intrinsic fluorescence coefficient $\beta$. Note that R6G/PBS corresponds to the fluorescence of rhodamine 6G in phosphate-buffered saline and that R6G/ALB/PBS corresponds to the fluorescence of rhodamine 6G in 2.5% bovine serum albumin–phosphate-buffered saline. (Reproduced by permission of the Optical Society of America, from Gardner et al.\textsuperscript{[127]})

Wu et al.\textsuperscript{[126]} have achieved a similar goal as Gardner et al.\textsuperscript{[127]} using a photon migration approach to model fluorescence from a homogeneous turbid medium such as tissue. The model provides an analytical relationship between the bulk fluorescence emission spectrum $F$ and the diffuse reflectance spectrum $R$ for arbitrary geometries and boundary conditions, which represents an advantage over the previous analytical model.\textsuperscript{[126]} Wu et al. demonstrate that the distortion can be removed by measuring $R$ from a turbid medium over the same wavelength range and with the same geometry as is used for measuring $F$. The validity of this approach has been demonstrated from tissue experiments using human aortic media and with Monte-Carlo simulations. This analytical model does provide accurate fluorescence line shape information, but unlike the previous analytical model\textsuperscript{[126]} the absolute intensity is still coupled to the absorption coefficient. This implies that the fluorescence measurements from two tissues that have the same amount of fluorophore but different amounts of absorption will have the same line shape but different fluorescence intensities.

Unlike Gardner et al.\textsuperscript{[127]} and Wu et al.\textsuperscript{[126]} Panou-Diamandi et al.\textsuperscript{[145]} modeled tissue fluorescence using electromagnetic theory. In this mathematical approach, the inelastic property of fluorescence was expressed via the polarization vector of the medium. The fluorescence scattering spectral function was independent of the excitation and emission geometry, expressing the energy transfer from the excitation frequency to all the emission frequencies. The model assumed that the tissue is a single, homogeneous, infinitely thick dielectric layer under plane wave illumination. Experimental measurements were carried out on optically turbid collagen gels that contained fluorescent dyes, in order to validate the mathematical model. Comparison between experimental and theoretically expected fluorescence emission spectra gave satisfactory results.

Another technique that has been employed to deconvolve the absorption and scattering properties from the fluorescence emission spectra of turbid media is partial least squares (PLS) regression.\textsuperscript{[146]} This method is not based on analytical approximations of the transport equations\textsuperscript{[126,127]} or Maxwell’s equations,\textsuperscript{[145]} but rather describes the fluorescence emission spectra measured from turbid medium as a linear combination of basis vectors that are representative of those to be predicted. The PLS method involves the regression between a fluorescence spectral matrix $X(n \times m)$ and a concentration matrix $Y(m \times p)$. PLS seeks a calibration matrix $B(m \times p)$ such that Equation (12) holds:

$$Y = XB$$  \hspace{1cm} (12)

The PLS method was compared to models of light transport based on Beer’s law\textsuperscript{[147]} and Kubelka–Munk theory\textsuperscript{[56]} to determine which is most effective in extracting the concentration of fluorophores in a set of turbid tissue phantoms containing absorbers and scatterers. The model based on Beer’s law significantly underestimated the fluorophore concentrations, whereas the model based on Kubelka–Munk theory significantly overestimated the concentrations. However, this method overestimated the concentrations by a constant scaling factor that potentially can be corrected for. Finally, using the PLS method, which was trained on a set of turbid tissue phantom spectra that have optical properties similar to those to be analyzed, fluorophore concentrations were predicted to within 5% of the true concentration.
complexity of the turbid media to be investigated. Several important obstacles remain before PLS can be applied to analyze fluorescence emission spectra from tissues. The main obstacle is the question of how to construct reliably a training set in which the concentrations of fluorophores and absorbers of biological interest can be quantified.

7.2.2 Identity and Distribution of Fluorophores that Contribute to Tissue Fluorescence Emission Spectra

It was mentioned earlier that quantification of the concentration of fluorophores within tissue in principle involves two steps. The first step requires deconvolution of the absorption and scattering properties of the tissue from the bulk tissue fluorescence emission spectrum. The second step requires knowledge of the identity and distribution of the fluorophores within the tissue. Although the previously described analytical models\(^{(126,127,145,146)}\) address the first step, they do not address the second. The following example addresses the second step specifically through the measurement and quantification of the biochemical and morphological basis of colonic tissue fluorescence emission spectra measured in vivo.\(^{(52)}\)

Zonios et al.\(^{(52)}\) measured and quantified the contribution of the fluorescent microstructures in frozen, unstained tissue sections to the tissue fluorescence emission spectrum measured from colonic tissues in vivo. In order to achieve this, first fluorescence emission spectra were measured at 370 nm excitation from normal colon tissues and colonic adenomas (precancer) in vivo. Deconvolution of absorption and scattering from fluorescence emission spectra measured from the tissues in vivo was achieved using optical properties obtained from Kubelka–Munk analysis of diffuse transmittance and reflectance measurements of excised human colon tissues in vitro. Fluorescence, microscopy and microspectrofluorimetry at 363 nm excitation of thin, frozen, unstained tissue sections were used to characterize the spectral line shapes and the distribution of the fluorescent microstructures that contribute to the measured fluorescence emission spectra of colonic tissues in vivo. A model based on Monte-Carlo simulations\(^{(65)}\) was used to relate the spectral line shape and distribution of the fluorescent microstructures to the colonic tissue spectra measured in vivo. This is perhaps one of the first comprehensive attempts to measure and quantify the biochemical and morphological basis of tissue fluorescence emission spectra measured in vivo.

The model developed by Zonios et al.\(^{(52)}\) describes the tissue fluorescence emission spectrum \(F(\lambda_x, \lambda_m)\), as shown by Equation (13):

\[
F(\lambda_x, \lambda_m) = \kappa \sum_i \phi_i(\lambda_m)D_i(z)T(\lambda_x, \lambda_m, z)dz
\]

where \(\lambda_x\) represents the excitation wavelength, \(\lambda_m\) represents the emission wavelength, \(z\) represents the depth within the tissue sample, \(\phi_i\) represents the intrinsic fluorescence of each individual microstructure with index \(i\), \(D_i(z)\) represents the fluorescence intensity spatial distribution of an individual microstructure with index \(i\), \(T(\lambda_x, \lambda_m, z)\) is a transfer function that incorporates the tissue optical properties and is calculated using Monte-Carlo simulations of light propagation in tissue, and \(\kappa\) represents a scaling factor.

First, a database of fluorescence line shapes and distributions of fluorescent microstructures within colon tissue were obtained. A microspectrofluorimeter incorporating a fluorescence microscope, an argon laser source (363.8 nm), a spectrograph and an intensified PDA, coupled to an optical multichannel analyzer was used to record the fluorescence emission spectra of microstructures from unstained, frozen tissue sections cut from tissue biopsies. Quantitative fluorescence imaging studies to quantify the distribution of the fluorescent microstructures within the tissue section were performed using a 75-W short-arc filtered xenon lamp (380 nm) coupled to a microscope and a thermoelectrically cooled CCD camera.

Finally, the transmission and reflection spectra of thick samples of normal mucosa and adenomatous polyps were measured in the range 300–700 nm using a spectrophotometer equipped with an integrating sphere. The tissue absorption and scattering properties were determined by calculating the Kubelka–Munk coefficients\(^{(61)}\) and transforming these into transport theory absorption and reduced scattering coefficients.\(^{(148)}\) The anisotropy parameter was obtained from the literature for tissues with histology similar to the colon.\(^{(53)}\) The transfer function was determined using Monte-Carlo simulations.\(^{(65)}\)

The transfer function accounts for the scattering and absorption of the excitation light and emitted light at wavelengths \(\lambda_x\) and \(\lambda_m\), respectively. It also accounts for the specific light illumination/collection geometry used to make the fluorescence measurements from tissues in vivo.

Figure 20 shows the computed fluorescence emission spectra of normal and adenomatous colon tissue versus the corresponding average fluorescence emission spectra measured from tissues in vivo. The peak intensity of the in vivo spectra has been scaled for comparison. The computed spectra contain all the characteristic spectral features observed in the in vivo spectra. The following interpretations may be made from the intrinsic fluorescent microstructures, the fluorescence density function and the transfer function used to calculate the computed fluorescence emission spectra shown in Figure 20:

- Although the intrinsic fluorescence of collagen (the dominant fluorophore) peaks at 420 nm, the observed peak in both normal tissues and adenoma is at 460 nm
The optical properties of skin, however, were obtained measured from excised skin tissue sections in vitro. The microscopic fluorophore distribution and spectra vivo using Monte-Carlo simulations in which they used They reconstructed the spectra measured from skin in vivo and the diffuse reflectance spectra of skin in vivo and the fluorescence emission spectra. Specifically, they measured the fluorescence emission and reconstructed in vivo skin fluorescence emission spectra.

Red fluorescence is increased in adenoma. This fluorescence intensity of adenoma is smaller than that of normal colon. This is due to three factors: the mucosal collagen fluorescence is decreased in adenoma due to the enlargement of crypts, which displace the lamina propria; the submucosa contributes to the fluorescence in normal tissue but not in adenoma, because of the increased thickness of a polyp; and adenoma exhibits increased absorption due to hemoglobin content.

The fluorescence intensity of adenoma is smaller than that of normal colon. This is due to three factors: the mucosal collagen fluorescence is decreased in adenoma due to the enlargement of crypts, which displace the lamina propria; the submucosa contributes to the fluorescence in normal tissue but not in adenoma, because of the increased thickness of a polyp; and adenoma exhibits increased absorption due to hemoglobin content.

Red fluorescence is increased in adenoma. This additional red fluorescence is primarily associated with the intrinsic fluorescence of the dysplastic crypt cells.

In conclusion, the model developed by Zonios et al. quantifies the contribution of the fluorescent microstructures that are responsible for differences observed in the fluorescence emission spectra of normal and adenomatous colon tissues. Their findings indicate that both the biochemical and morphological features of the tissue contribute to the measured fluorescence emission spectrum.

Zeng et al. have used a similar approach to reconstruct in vivo skin fluorescence emission spectra. Specifically, they measured the fluorescence emission and diffuse reflectance spectra of skin in vivo and the fluorescence of the microstructures in the skin in vitro. They reconstructed the spectra measured from skin in vivo using Monte-Carlo simulations in which they used the microscopic fluorophore distribution and spectra measured from excised skin tissue sections in vitro. The optical properties of skin, however, were obtained from published values in the literature. They did not report similar data for any skin lesions such as naevi or melanoma.

7.3 Effect of Excitation and Emission Geometry on Fluorescence Emission Spectra of Turbid Media

Several groups have evaluated the effect of the excitation and emission geometry on the measurement of tissue fluorescence emission spectra from turbid media and tissue. Keijzer et al. used Monte-Carlo simulations and experimental measurements to show that the illumination/collection geometry affects both the intensity and line shape of fluorescence emission measured from tissue. Specifically, they demonstrated that as the separation between the illumination and collection fiber is increased, the measured fluorescence intensity decreases as a result of hemoglobin absorption. Furthermore, the attenuation due to hemoglobin absorption is wavelength dependent, thus affecting the fluorescence line shape as well. Richards-Kortum et al. suggested using a fiber-optic probe, which collects the emitted light from an area, that is directly illuminated by the excitation light in order to minimize the effect of hemoglobin absorption on the fluorescence measurement. Qu et al. also used Monte-Carlo simulations and experimental measurements to demonstrate that the distortion to the fluorescence emission spectrum is a function of the diameter of the area viewed by the illumination and collection fiber as well. Using bronchial tissue optical properties (for the excitation and emitted light) in their Monte-Carlo simulations, they found that the distortions to the fluorescence emission spectrum were minimized when the diameter of the tissue area viewed by the excitation and emission fiber was less than 1 mm. This was verified experimentally.

Pogue et al. went a step further and demonstrated that if fluorescence is measured from a sample volume that is smaller than the average mean free scattering path (inverse of the reduced scattering coefficient) within that turbid medium, then the effects of absorption will be diminished. To achieve this, they used a confocal detection scheme to measure fluorescence as a function of fluorophore concentration from a turbid medium. They used a pinhole detector with a diameter (10 µm) that was an order of magnitude smaller than the mean free scattering path in the medium. Using this method, they were able to obtain a linear relationship between the fluorescence intensity and concentration of the fluorophore in the turbid medium for a wide range of fluorophore concentrations. Although this relationship was independent of the absorption coefficient, the fluorescence intensity varied linearly with the scattering coefficient for a fixed fluorophore concentration. Fortuitously, this is not a serious limitation because most tissues do not have a large variation in their scattering coefficient. It was also observed...
for a fixed detector size that, as the mean free scattering path decreases, the number of nonscattered fluorescent photons relative to the number of scattered fluorescent photons that are detected also decreases. This suggests that the size of the detector has to be reduced as the mean free scattering path length of the turbid medium is reduced. This has direct implications on the strength of the fluorescence intensities detected and the size of the sampled volume. In a subsequent report, Pogue et al.\textsuperscript{152} showed that they could overcome the problem of poor signal-to-noise ratio by developing and employing a fiber-optic probe that has multiple fibers (100 µm in diameter), each of which serves as an independent source and detector. Using this probe, the fluorescence intensity measured by each fiber was obtained from a sample volume smaller than the mean free scattering path for that medium, thus minimizing the effect of absorption. By integrating the fluorescence intensity from a total of 30 fibers, the signal-to-noise ratio of the fluorescence measurements was enhanced significantly. The main limitation of this technique is the very small sampled volume.

Avrillier et al.\textsuperscript{153} used an alternative approach to resolve the effect of the illumination/collection geometry on the fluorescence emission spectra of tissue. They used Monte-Carlo simulations and optical properties of tissues measured in vitro to predict the effect of absorption and scattering on the tissue fluorescence emission spectra measured in vivo. Specifically, they predicted the correction factors as a function of increased separation between the excitation and emission fibers. These predictions were used to correct the distortion in the fluorescence emission spectra measured from the tissues. However, because the optical properties of tissues measured in vitro are fraught with error associated with extraction, this approach is considered to be, at best, approximate unless the tissue optical properties used in the Monte-Carlo simulations are measured in vivo.

8 FUTURE PERSPECTIVES

Diagnostic tools based on optical spectroscopy in the UV/VIS spectral regions have the potential to link the biochemical and morphological properties of tissues to individual patient care. In particular, these techniques are fast, noninvasive and quantitative. Furthermore, the accuracy and efficacy of the technology have been demonstrated clinically to be comparable or superior to current clinical modalities.

However, the biochemical and morphological basis for the diagnostic capability of fluorescence spectroscopy is not completely understood. This is limited by the lack of sophisticated mathematical models that can be used to quantify tissue optical properties in order to account for the effects of absorption and scattering in the UV/VIS spectral region; and a comprehensive understanding of the biochemical constituents that contribute to the measured fluorescence. Hence, today’s challenge for biomedical optics is to elucidate tissue biochemistry and morphology in greater detail for the specific disease process so that appropriate therapeutic interventions may have the greatest impact. In order to achieve this, both experimental and mathematical techniques need to be developed that can enable a greater understanding of the chromophores and fluorophores that are modulated by the disease process and their contribution to the measured spectrum.

Animal models are useful with regard to developing methodologies that can be used to elucidate the biochemical and morphological properties of tissue and optimizing the instruments to exploit these features. The advantages that they offer are: they are well characterized; spectral measurements can be made per tissue site for a variety of experimental and biological conditions; and data can be obtained from a statistically significant number of animals for the purpose of validation without the need for expensive clinical trials. Although animal model studies have been performed extensively in relation to the use of photosensitizing agents for PDT, only a handful of studies on measuring and quantifying tissue autofluorescence have been performed.\textsuperscript{154–159}

With respect to clinical applications, the diagnostic potential of fluorescence spectroscopy is defined by histology. In order to evaluate if fluorescence spectroscopy is sensitive to changes that precede the morphological manifestations seen by histological evaluation, it is valuable to correlate the measured spectral information to other biochemical and/or genetic markers of increased cancer risk. Furthermore, although fluorescence spectroscopy has been most widely explored for the detection of precancer or cancer in a screening and diagnostic setting, its diagnostic potential for guiding surgery has been evaluated only in a limited number of clinical studies.\textsuperscript{101} Because this technique can discriminate between diseased and nondiseased tissues in a fast and noninvasive manner, it could be used to define margins of resection for various surgical procedures, such as that of the breast and brain. Additionally, this technique also could be used to monitor the response of tissues to various therapeutic interventions.

In vivo glucose sensing and regulation is necessary for patients with carbohydrate metabolism disorders, particularly those caused by diabetes mellitus. Self-monitoring of blood glucose is part of the daily routine for such patients, and the measurement of capillary blood glucose, using different enzymatic assays in combination with photometric or electrochemical detection, still remains the standard method. Research activities concentrate on developing minimally invasive and noninvasive methodologies, the latter being based on spectroscopic techniques exploiting optical glucose specific characteristics, i.e. wavelength-dependent absorptivities and refractive indices, mainly in the near-infrared (NIR), or the rotation of linearly polarized radiation in the visible range. Owing to the complexity of the integrally probed tissue, and the presence of many interfering compounds, only multivariate spectroscopic measurement strategies, using several wavelengths, can be used for a noninvasive in vivo assay of glucose. Further complications arise from the heterogeneous distribution of glucose in the intravascular, interstitial and intracellular space and differences in their dynamics. In contrast to the established reference methodology which uses capillary blood, especially for the hypoglycemic concentration range, the imprecision observed so far within several experimental optical approaches is regarded as unacceptable for patient self-monitoring. Further research is needed to establish an in vivo glucose assay for diabetic patients, or for direct monitoring in intensive care units and operating theatres, based on optical spectroscopy.

1 INTRODUCTION

All vital processes in cells or larger organisms require a source of energy and the supply or removal of essential substances. In this context, aldohexose glucose is a substance of great metabolic importance, because it can be considered as the main energy carrier for the human organism, and is the most abundant monosaccharide in physiological samples. D-Glucose can be found in two different stereoisomers, i.e. the $\alpha$- and the $\beta$-anomeric form. In aqueous solution each form slowly changes, by means of the free aldehyde, into an equilibrium mixture of approximately one-third of $\alpha$-D- and two-thirds of $\beta$-D-glucose (1), a process which is called mutarotation. Due to their chirality, both isomers show different optical activity and may exhibit dissimilar properties in enzymatic reactions.

In the fasting human body at rest, much of the utilized glucose is consumed by the brain and the nervous system, while erythrocytes account for much of the remainder. To avoid large fluctuations of blood glucose, an endocrine regulation exists, a mechanism for which the term homeostasis was coined. The hormone insulin, which is secreted by the B cells of the islets of Langerhans in the pancreas, plays a particularly important part in lowering the glucose concentration. Other effects will also be discussed.
Owing to the importance of D-glucose, most analyses in a clinical laboratory are concerned with this sugar. Continuous measurements are carried out, for example, in critical care units when bedside monitoring of severely ill patients is performed. Furthermore, measurements of glucose are essential for patients without adequate glycemic control, which leads to enormous and adverse variations in blood glucose concentrations. Disorders within carbohydrate metabolism are frequently found, especially diabetes mellitus. About 6% of the adult population in developed countries is affected by this metabolic disease, and there are estimates that as many as 120 million people worldwide suffer from diabetes. According to the World Health Organization there are different categories of diabetes, of which the dominant primary one exists in two different forms, Type I and Type II diabetes.

Type I diabetes, also known as insulin-dependent diabetes mellitus (IDDM), often starts during childhood, and accounts for about 5–10% of the diabetic population. It is caused by an autoimmune disease and is characterized by a complete insulin deficiency due to the destruction of the beta cells producing the hormone.

In Type II diabetes, enough insulin may be available but, due to insulin resistance of the target organs, homeostasis is perturbed. A second mechanism, manifested by progressively diminishing insulin release, can also be responsible for the increase in plasma glucose concentration. This type is often called noninsulin-dependent diabetes mellitus (NIDDM), and occurs mainly in people over 40 years of age.

For all diabetic patients the medical therapy aims to regulate glucose levels to those of metabolically healthy individuals. The results from intensive studies within the Diabetes Control and Complications Trial\(^1\) or the UK Prospective Diabetes Study\(^2\) recommended treatment programs designed to achieve normal or near-normal glycemia (intensified insulin therapy for insulin-dependent diabetic patients), which demands frequent testing of blood glucose. Without proper management, this disease can lead to severe long-term health complications, including perturbations in the microcirculation of blood, with associated blindness, kidney and heart diseases, nerve damage and finally amputation of extremities.

Patient self-monitoring certainly represents the greatest advancement in diabetes therapy since the discovery of insulin. In current practice, diabetics prick a finger with, for example, a lancet, take a drop of blood, and place it on a dry chemical test strip, which is either visually or instrumentally evaluated (also called color reflectance technology). Recent biosensor technology has provided miniaturized alternative equipment that utilizes electrochemical measurements (amperometry). Further development of blood glucose meters aims at using only a few microliters of blood, providing the analysis result within a minute and faster. For a better understanding of the requirements for the development of in vivo glucose assays, some fundamental aspects will be discussed first. Since spectroscopic assays are presented, substances containing carbohydrate moieties showing spectral similarity to the free glucose are worth mentioning.

### 2 MEDICAL AND ANALYTICAL ASPECTS

#### 2.1 Carbohydrate Metabolism

The principal product of carbohydrate digestion is glucose, which can be found in peripheral venous blood at a concentration of 70–110 mg dL\(^{-1}\) (3.9–6.1 mmol L\(^{-1}\)). In arterial blood, the plasma glucose level is between 15 and 30 mg dL\(^{-1}\) higher than in venous blood. The arteriovenous level difference usually depends on nutritional and metabolic conditions. Glucose, upon entering the cells, becomes phosphorylated to glucose-6-phosphate, after which it may be catabolized. Phosphorylation is actually the initiating reaction for glycolysis, where the citric acid cycle is the final pathway for the oxidation of carbohydrates to CO\(_2\) and H\(_2\)O. The metabolism of glucose leads to the intermediate reaction product of pyruvate, which gives lactate following reduction. The latter reactions are carried out under anaerobic conditions, i.e. in the absence of O\(_2\). The production of glucose (gluconeogenesis) from amino acids and glycerol in the liver is also possible.

Another pathway for the depletion of glucose is by the synthesis of macromolecules. In particular, glycogen, a storage form of glucose which is mainly found in the liver and skeletal muscles, is of great importance. The blood also contains glycogen at an average concentration of 27.5 mg L\(^{-1}\), mainly in the granulocytes (45%) and in the platelets (45%). A pathway within skin tissue allows the synthesis of mucopolysaccharides. In principle, the medical physiology and biochemistry concerning glucose is rather complex and is beyond the scope of this article. For more information, see Ganong.\(^3\) In Figure 1 the significant factors that influence plasma glucose levels are sketched. Renal excretion usually takes place when the venous plasma glucose concentration is above 180 mg dL\(^{-1}\), which explains why glucose in urine remains an index component of metabolic disorders in patients. Utilization of glucose by the brain, muscles and other tissues, its metabolic activities in the liver, or its transformation into neutral fat, stored in adipose cells as a long-term energy reserve of the body, must also be mentioned. Modeling the homeostasis of blood glucose
concentration is indeed complicated, and problems have been discussed by other authors.\textsuperscript{4,5}

The principal determinants for glucose entering and leaving the bloodstream are dietary intake, rates of entry into different tissues and the glucostatic activity of the liver. An increase in insulin plasma concentration causes more glucose to be stored, whereas glucagon, another peptide secreted by the A-cells of the islets of Langerhans, shows reciprocal hormonal activity, mobilizing glucose. Excess insulin causes hypoglycemia (lower than normal blood glucose concentration), which can lead as a first complication to unconsciousness. Chronic hyperglycemia (higher than normal glucose concentration) can cause coma and death due to so-called acidosis and dehydration of the body. In the longer term, it leads to nonenzymatic glycation of proteins inducing cellular dysfunction and modifications of the extracellular matrix. After glycation and further transformation, advanced glycation endproducts (AGE) are formed.

A fraction of the blood hemoglobin also becomes glycated. Normally, hemoglobin in adults is found as two variants, HbA1 and HbA2 (the A indicates adult). Hemoglobin consists of 97.5% HbA1 (molecular weight of 64,450). Glycation commences with the nonenzymatic formation of an aldimine (Schiff’s base), which is labile. It follows an irreversible rearrangement to the stable ketoamine form. At normal blood glucose concentration, the glycated hemoglobins account for about 6–8% of the total hemoglobin. Owing to the life time of the erythrocytes, an indicator for the mean blood glucose concentration over the previous 10–12 weeks is provided by the glycohemoglobin fraction HbA1c, which is the major glycohemoglobin. It is biochemically characterized as the stable adduct of glucose to the N-terminal valine within the two polypeptide β-chains [N-(1-deoxyfructosyl)hemoglobin] with a reference range of 4.5–6.3% of total hemoglobin for healthy individuals. For diabetic persons, the HbA1c fraction is usually elevated to 8% and higher, with values sometimes exceeding 10%. An increase of 4% in this value gives an equivalent concentration of bound glucose of about 4 mg dL\textsuperscript{−1}, compared with the glycated hemoglobin fraction normally found. Albumin is also glycated, but is metabolized more rapidly, which allows it to be used as an indicator of more recent average glucose levels.

It must be remembered that sugar moieties of mammalian glycoproteins show significant variations in their structure and relative occurrence during growth, development and differentiation due to their presence in many biological functions. This must be kept in mind when assaying body fluids and tissues by spectroscopic methods. For blood, analytical results for total carbohydrates, bound to proteins, were reported as 2.7 g L\textsuperscript{−1}, with hexoses alone providing a level of 1.2 g L\textsuperscript{−1}.\textsuperscript{6}

(b) Glucose profiles for two male diabetic subjects; and (c) glucose profiles for a third male diabetic subject with experiments on two different days.}
\end{figure}
The dynamics of changes in blood glucose concentration are of special interest for in vivo assays, since they dictate the necessity for assay speed and timing. In Figure 2 some experiments are presented with deliberately induced changes. Under such conditions it is also usual for calibration experiments for in vivo assays to be carried out. For the clinical diagnosis of diabetes, the response to a standard test dose of glucose is evaluated, a procedure which is called the oral glucose tolerance test (OGTT). Usually, the adult being tested is given a sugar solution equivalent to 75 g of glucose. In healthy individuals the fasting plasma glucose level is less than 115 mg dL\(^{-1}\), and the 2-h value less than 140 mg dL\(^{-1}\) with no further rise above 200 mg dL\(^{-1}\). Values between 140 and 200 mg dL\(^{-1}\) during the first 2 h of the test indicate an impaired glucose tolerance. Such tests are shown in Figure 2(a) with the results from a healthy person and a woman who shows the possibility of impaired glucose tolerance (the glucose load was larger than in standard oral glucose tolerance testing). The results shown in Figure 2(b) and (c) below were obtained from diabetic patients. Their 2-h blood glucose values are all higher than 200 mg dL\(^{-1}\). It is noteworthy that for some periods very sharp changes in glucose concentration occur (about 40 mg dL\(^{-1}\) per 10 min), which exemplifies the need for a rapidly responding sensor system.

2.2 Glucose in Blood and Tissue

A noninvasive and painless measurement assumes that blood sampling is unnecessary. Obtaining quantitative analytical information concerning metabolites by using transcutaneous in vivo spectroscopy of body tissue poses many practical problems. Most information, as discussed above, is gained from sampled blood, which represents only a relatively small fraction of the tissue volume under investigation. This fraction is not well known and may vary considerably depending on the location and the physiological state of the microvasculature. Generally, about 70% of the total blood volume is related to the venous vasculature, 20% is arterial and about 5% is capillary blood. The arterio-venous glucose difference also plays a role in integral tissue probing within spectroscopic assays. Under physiological conditions, the difference can vary considerably as a result of nutritional and metabolic activities. After glucose intake during oral glucose tolerance testing a maximum difference of 45 mg dL\(^{-1}\) (2.5 mmol L\(^{-1}\)) has been found. Additionally, the blood flow in response to thermoregulatory stimuli can vary between 1 and 150 mL per 100 g of skin tissue, which greatly affects the arterio-venous difference.

For transcutaneous in vivo measurements, the most suitable tissue has to be selected on the basis of possessing a high fraction of blood within its composition. For human skin at different measuring sites, at a given skin temperature, the tip of the index finger showed the highest hemoglobin concentrations which could be related to the tissue blood volume. Our own measurements showed that the human lip was an even better test location for the same reasons (see Figure 3). In Figure 3(a) the diffuse reflectance spectra of different skin tissues are presented, which are dominated by the absorption features of oxygenated hemoglobin (hemoglobin oxygenation saturation, HbSO\(_2\), is usually high at around 90%). Figure 3(b) shows the effect of hyperemization of the inner lip tissue by applying a fiber sensor head thermostated at 42 °C, leading to an increase in blood volume and hemoglobin oxygenation. Figure 3(c) illustrates the effect of external pressure applied to the skin tissue, pushing blood out of the probed tissue.

In addition to the intravascular fluid, the interstitial fluid, bathing the different cells, belongs to the extracellular body water compartment. It provides nutrients and oxygen to the tissue and takes up metabolic waste products. The constituents of the interstitial fluid are constantly replenished by the blood. Some fluid from the interstitial space is steadily removed by the lymphatic system. Interstitial fluid is a passive medium with virtually no flow.

The percentage of the intravascular, interstitial and intracellular compartments is tissue dependent. The volume of interstitial fluid, compared to the whole body, is about three times greater than the plasma volume, but the amount of interstitial fluid in a tissue depends on the pressure in the capillaries, the oncotic pressure, the capillary filtration coefficient, the number of active capillaries, the lymph flow, and the total extracellular fluid. However, no significant changes in the concentration of low molecular weight compounds in plasma were found when the plasma volume was decreased by orthostasis. For spectroscopic limb measurements, fluid values of 63% for the intracellular and 37% for the extracellular space were reported, where 27% related to the interstitium and 10% to blood plasma. A model calculation for glucose tissue average was presented for a blood glucose value of 100 mg dL\(^{-1}\), leading to a tissue average of 38 mg dL\(^{-1}\), with more than half of the glucose related to the interstitial fluid (58%), less than a third to blood (26%), and 16% due to the intracellular fluid.

For various reasons it is apparent that the composition of the interstitial fluid is similar to plasma, but some temporal relationships for the concentration profiles of different metabolites can be expected. The physiological balance differs in each of the compartments, and response times to drastic changes in the vascular compartment pose.
may vary due to the physiological condition, such as blood circulation. For glucose, concentration differences between blood and the subcutaneous (s.c.) or dermis interstitial fluid also exist.

There is still controversy concerning the absolute glucose concentration in the interstitial fluid, when compared to that of blood. Some investigators, using microdialysis probing, claim the s.c. interstitial glucose concentration, under steady state conditions, to be practically identical to that in blood, whereas other authors have found values of only about 75% of the blood glucose concentration, which supports the theory of glucose extraction by the peripheral tissue. In a recent review, the results from many different investigations were compiled and experimental effects from different analytical probes were discussed. According to theory, the physiological diffusion delay is caused by a change in the diffusion equilibrium as obtained under steady-state conditions. This change can be triggered, for example, by a sharp rise in blood glucose concentration under the same cellular glucose utilization rate. Thus, the physical transfer of glucose from blood, through the interstitial space to the cells, is maintained. The modeling of stationary glucose diffusion processes from a central capillary to the neighbouring tissue under constant cellular glucose utilization, the so-called Krogh’s cylinder model, in addition to the time-dependent diffusion processes, have been described previously. Key parameters are the diffusion constant, vessel diameter and spatial capillary density, allowing the calculation of average tissue concentrations.

We have been modeling the transport processes by using moving average filters or impulse-invariant designed Butterworth filters of the first order. The
delays seen by taking the diffusion processes and the cellular glucose utilization into account were dependent on the rate of blood glucose changes and glucose extraction, which may explain some of the large variations seen within lag-time studies. A model calculation is given in Figure 4(a), where the time-dependent traces of blood glucose and that of an average tissue measurement are shown. Figure 4(b) provides absolute differences, particularly in the hypoglycemic range, where systematic errors are relatively large for estimating a blood glucose level from an integral tissue measurement. For changes in the concentration profiles, delays between 10 and 20 min in relation to glycemia were observed. In addition, the impoverishment of glucose in a tissue can precede hypoglycemia, which can be used as an early marker.\textsuperscript{[12,13]} It was possible to model such effects by taking standard glucose diffusion and different cellular glucose uptakes into account.

Blood flow cannot be neglected as a variable in interstitial glucose studies (see literature in Roe and Smoller\textsuperscript{[9]}), although the reduction of gradients within the tissue, e.g. along the blood capillaries, is certainly a factor which accounts for an increase in integral tissue glucose, particularly in skin tissue. Skin is very sensitive to circulatory shunting effects, as seen in Figure 3(b), and the rise in blood flow parallels vasodilation, equivalent to an increase in blood volume.

The permeability of the capillary walls is crucial to the rate of metabolite exchange between blood and interstitial fluid. Diabetes is known to affect the vasculature, and vast changes in the microcirculation can occur with disease progression.

2.3 Conventional Assays Based on Invasive Technology

Despite the abundance of diverse test strip devices for blood glucose measurement, the support of a clinical chemistry laboratory is still required. In the past, it had been the exclusive task of such a laboratory to analyse blood or other body fluids. Since blood serves as the primary metabolic transport system within the body, medical interest focuses on monitoring its metabolite concentrations as a guide to the metabolic state. Other fluids, such as urine, saliva, sweat and tears, have also been analysed for glucose, but no useful correlation with the concentrations in blood could be established, although glucose in urine is used as an index component for metabolic disorders.

Before the advent of enzymatic and spectroscopic assays, a variety of chemical methods\textsuperscript{[14]} had been developed for glucose analysis, whereas enzymatic procedures are generally used nowadays in clinical and food laboratories.\textsuperscript{[15]}

Enzymatic methods are widely used for reference analysis, necessary for calibrating spectroscopic assays. For glucose determination three enzyme systems are commercially available. The hexokinase (HK) method has been internationally recommended as a reference method. Here, a two-step reaction is necessary: in the first reaction HK (EC 2.7.1.1) is used, followed by an indicator reaction catalyzed by glucose-6-phosphate dehydrogenase (G-6-P-DH; EC 1.1.1.49), which provides the specificity of the method. The second common method uses glucose dehydrogenase (G-DH; EC 1.1.1.47), which requires the addition of mutarotase, accelerating the conversion of the anomic $\alpha$- into the $\beta$-form of D-glucose. A third method uses the enzyme glucose oxidase (GOD; EC 1.1.3.4), which catalyzes the oxidation of glucose to gluconic acid providing H$_2$O$_2$. An indicator reaction is usually necessary for quantification by spectrophotometry. Other detection methods follow oxygen consumption (e.g. by using the Clark electrode) or the formation of hydrogen
peroxide amperometrically. Assay kits are commercially available, and various automated analyzers have been developed.

Many electrochemical biosensors are based on these measurement principles allowing in vivo or ex vivo glucose measurements. Similarly, solid-phase reagent systems for self-monitoring of blood glucose rely on enzymatic methodology. These systems have the advantage that the chemical reaction products can be evaluated visually, or with greater precision by means of a reflectance photometer. The availability of reagent strips and pocket-sized reflectance meters has had considerable impact on the management of diabetes, allowing a more specific therapy. This technology is now challenged by biosensory methods, which require sample volumes of only a few microliters.

The usual invasive methods of sampling disrupt the skin barrier and puncture the capillary bed in order to draw a blood sample. The current trend is certainly to enable minimally invasive measurement of physiological analytes. An emerging technology uses reverse iontophoresis to electroosmotically extract body fluid with glucose. Thermal microporation and suction have both been proposed for interstitial fluid harvesting, but these competing techniques still face various problems for in vivo assays. For reviews see Roe and Smoller and Klonoff.

At present, intermittent invasive testing is widely practised, although continuous monitoring offers many advantages, since a glucose sensor could be coupled to an insulin pump, thus completing the artificial pancreas. Therefore, much effort is currently under way to develop sensors for continuous monitoring. However, invasive in vivo sensors face the problem of biocompatibility, which usually compromises the performance of the sensing device. In addition there is the risk of infection, and the implantation into the vascular space, as an option for long-term monitoring, is not advisable due to the formation of thrombi, as this could present a major health risk to the patient. Another approach may be the implantation of an electrochemical biosensor into the subcutaneous tissue. An alternative to intravascular measurement is the analysis of the interstitial fluid, but complications have been reported for such in vivo sensing. However, ex vivo sensor applications avoid these problems by using microdialysis probes, although this is at the cost of a dilution of the fluid under investigation. Other systems proposed for on-line continuous ex vivo monitoring rely on open tissue perfusion. In the longer term, noninvasive technology, based, for example, on NIR spectroscopy, will be available for intermittent and continuous monitoring of blood glucose concentration. The benefits of this are obvious, because such a transcutaneous measurement is painless, and does not require a blood sample to be taken.

### 3 OPTICAL SPECTROSCOPY FOR IN VIVO MEASUREMENTS

#### 3.1 Optical Glucose Sensing

Many medical instruments, including those for magnetic resonance imaging and spectroscopy, rely on the interaction of electromagnetic radiation with body fluids and tissues. The same is true of optical techniques, which find numerous applications in the medical field and offer the potential for the development of small, rugged and moderately priced instruments. The use of infrared (IR) spectroscopy for biomedical applications has increased tremendously in recent years. One objective is to develop IR spectroscopic methods for medical diagnostics (IR pathology) in order to investigate the transformation from healthy to diseased cells and tissues. Quantitative analysis of body fluid constituents is another major field in clinical chemistry where optical analytical methods may find a use.

Generally, spectroscopic methods exploit specific optical characteristics of the analyte, e.g. wavelength-dependent absorptivities or refractive indices, mainly in the NIR or, as for optically active glucose, the rotation of linearly polarized radiation. For in vitro and in vivo assays, IR, Raman spectroscopy and other optical techniques such as polarization, scattering and photoacoustic approaches have recently been proposed for measuring glucose concentrations in blood, interstitial fluid, tissues or the aqueous humor of the eye. Many of these methods have worked well for carefully controlled in vitro samples, e.g. blood plasma or other body fluids. However, in vivo measurements are confounded by large variations in tissue physiology, including a greater sample complexity and microheterogeneity as well as spectral artifacts caused by the optical properties of tissues.

The Raman effect involves inelastic radiation scattering, which results in a characteristic spectrum. The photoacoustic NIR measurement technique has also been used and promising results were recently published by MacKenzie et al. A further technique currently under investigation is fluorescence spectroscopy. Usually, the specimens studied are multicomponent systems, with individual components contributing many overlapping signals. Such a situation requires the application of multivariate techniques, such as measurement at several wavelengths and chemometric methods to determine concentration. Until now, the NIR absorption approach has been shown to be the most effective method of proving in vivo blood glucose monitoring capabilities, and this method will be presented in more detail. Finally, results from novel techniques using pulse spectrometry (NIR photoplethysmography) are discussed. In the final section, some optical techniques are reviewed and their
impact on the development of in vivo assays of glucose is discussed.

3.2 Near-infrared Spectroscopy

For quantitative analysis, the mid-IR and NIR spectral ranges are of special importance. In the mid-IR (2.5 μm–25 μm; 4000–400 cm⁻¹) significant absorptions caused by excitation of molecular vibrations assigned to fundamental and combination bands occur. Such absorptions are characteristic of a molecule and are useful for identification. In the NIR range (780–2500 nm; 12 800–4000 cm⁻¹) molecules absorb radiation for excitation of overtone and combination vibrations. The most intense bands are mainly from vibrations of molecular moieties that involve hydrogen atoms, e.g. O–H, C–H and N–H. The short-wave near-infrared (SWNIR) carries higher overtone bands with even smaller absorptivities, so that the optical sample pathlength is usually increased, and aqueous solutions can be measured with cuvettes of 1-cm pathlength. The visible and the SWNIR range exhibit significant absorption bands due to electronic transitions.

In Figure 5, some NIR spectra of substances measured mainly as crystalline powders are shown. These are important in the analysis of blood, and the individual bands can be assigned to certain vibrations of molecular substructures.² The intensities of the higher overtone vibration bands decrease compared to lower overtone bands. This becomes clearer when the spectra of small, simply structured molecules are interpreted. In Figure 6(a) a comparison between glass-like glucose, which gives a similar spectrum to that in aqueous solution, ethanol and hexane is given, and the assignment of bands involving hydrocarbon subunits and C–OH groups is evident through the corresponding band frequencies. In the glucose spectrum, the band indicated with an asterisk at around 5200 cm⁻¹ belongs to some water residue. SWNIR spectra recorded at 1-cm pathlength contain similar structural information (Figure 6b).

For different classes of compounds, NIR spectra show significant differences. Frequently, substances with similar structures, which could easily be quantified by using enzyme methods, have to be determined, but the similarity of their NIR spectra can lead to a failure of the spectroscopic assay. Of particular importance are the monosaccharides found in biosystems. For example,
the spectra of crystalline glucose, fructose and galactose (Figure 7a) show impressive differences which can be used advantageously for substance identification. Quite different features exist when glass-like samples from syrup preparations and samples after the evaporation of water are studied (Figure 7b). These spectra are similar to those obtained from difference spectroscopy of aqueous solutions to be discussed later. The largest spectral differences are found at a spectral range around 4000 cm\(^{-1}\). This is the reason why many researchers favor this spectral range, as it can be used for aqueous samples by utilizing cuvettes of about 0.5-mm optical pathlength.

The biomedical samples considered here contain water as the main constituent, and its optical properties, in particular the characteristics of its radiation absorption in terms of the absorption coefficient, dominate the IR spectra. An interesting experiment is the follow-up of the evaporation of water in whole blood by diffuse reflectance, the spectra of which are shown in Figure 8. The disappearance of the water absorption bands is evident and finally, spectral features from proteins such as hemoglobin and albumin dominate the dry film spectrum.

The quantitative investigation of biofluids by multivariate IR spectrometry can be carried out successfully, and novel assays for reagent-free multicomponent analysis have been presented in the literature. Whole blood is certainly the most frequently studied fluid, but other liquids such as aqueous humor, urine, saliva and synovial fluid have been analyzed by spectroscopic methods. For literature reviews, see Heise et al.\(^{(19)}\) and Khalil.\(^{(20)}\)

As water plays an important role in spectroscopic bioassays, some further characteristics are discussed in order to better understand the challenges encountered when devising in vivo assays. Figure 9(a) shows the water spectra recorded when two cells of different optical pathlength were used. The spectra illustrate the intense absorptions caused by H–O–H overtone and combination vibrations. In addition, the hydrogen bonding network of the water molecules in the liquid phase must be considered, as it leads to a tremendous broadening of the absorption bands due to variations in the molecular force field and structure that result from the intermolecular interactions. The association equilibrium between water molecules is very sensitive to temperature change, which can be estimated from spectral changes seen in Figure 9(b) and (c). This is the reason why spectroscopic in vitro experiments are usually carried out under cell thermostating. On the other hand, the temperature dependencies of the
The NIR water spectrum can be exploited for temperature determination.

Additionally, the hydrogen bonding between the water molecules is influenced by electrolytes and, to a rough approximation, the change in the IR spectra of aqueous solutions is similar to that caused by a change of temperature of pure water (Figure 9b and c). The linear dependencies exhibited by the water spectrum can be used under special conditions for determining NaCl concentration. By using the NIR spectra of aqueous solutions the measurement of pH is also possible, and titrations have been followed by NIR spectroscopy.\(^{(21)}\)

Similarly, strong interactions between water and biopolymers can occur, which also affect the hydrogen-bonded water clusters, leading to some significant shifting of water absorption bands. Proteins are particularly prone to such interactions. For example, collagen, in the form of gelatine or cartilage, and polysaccharides, such as dextrin and hyaluronate, can easily be hydrated. Recently, the water in skin has been studied in detail with respect to such effects.\(^{(22)}\) This clearly demonstrates the complexity of water spectra and the numerous factors which must be considered when using NIR spectroscopy for the analysis of biofluids.

The spectra of several compounds in aqueous solution, of particular interest for the in vivo glucose assay, are presented in Figure 10. Here, again, absorbance spectra within the SWNIR and the conventional range are highlighted using transmission cells of appropriate pathlength. The difference spectra were compensated for the absorbance of water by using a spectrum of pure water, but due to the interactions between solute and solvent the compensation is incomplete (note the sharp spectral dips at the position of the water bands). As discussed, apart from differences above 4000 cm\(^{-1}\), there are large spectral similarities. An interesting compound is hydroxyethyl starch, which is water soluble and used medically as a blood plasma substitute for reducing blood viscosity or compensating for blood loss. The spectral features of the polysaccharide are due to glucose subunits, and resemble those of glycogen. Another compound, ethanol, whose spectrum is given in Figure 6 can be found in blood after consumption of alcoholic beverages. There are certain conditions where the a priori knowledge of the absence of such substances is critical as their presence could lead to large perturbations in assay performance. See, for example, Berentsen.\(^{(23)}\)

Owing to the large water absorptivities in the mid-IR, penetration of IR radiation is not sufficient to establish transcutaneous measurements of metabolites in tissue, in particular when the so-called attenuated total reflectance technique is applied for in vivo measurements.\(^{(24)}\) This problem may be overcome by using NIR spectroscopy for
which the water absorptivities are much smaller. Due to the optical constants of tissue, i.e., the spectral absorption and scattering coefficients, a wavelength-dependent penetration depth for such radiation exists. For wavelengths between 600 and 1300 nm (16 700–7700 cm\(^{-1}\)), the so-called therapeutic window) transmission measurements of body tissues are possible.\(^{(25)}\) The spectral range above these wavelengths, in particular the interval between 1600 and 1850 nm (6250–5400 cm\(^{-1}\)), is dominated by two water absorption bands, and is accessible by diffuse reflectance measurements,\(^{(26)}\) due to the tissue scattering characteristics.

Figure 11 shows several spectra of lip mucosa, which was chosen as an example of soft tissue, obtained using different instrumentation (more details on tissue optics and spectroscopy are given in later sections).

### 3.2.1 Instrumentation and Novel Developments

Different types of spectrometer are used for NIR spectrometry, and there is a growing trend towards miniaturization. In the past, scanning grating spectrometers were the most widespread. Originally, NIR spectroscopy was carried out by extending the range of ultraviolet/visible (UV/VIS) instrumentation. Nowadays, many instruments are based on polychromators with diode arrays to measure the whole spectrum simultaneously. Other NIR measurement technology uses acousto-optical tunable filters. An acoustic wave is

(a) NIR data from solutions of 1.5% concentration recorded at 30°C with 0.5-mm pathlength (HES, hydroxyethyl starch). (b) SWNIR spectral range recorded from solutions of 0.5% concentration each recorded at 30°C with a 10-mm pathlength cell. (Reproduced by permission of American Institute of Physics, from H.M. Heise, A. Bittner, *Fourier Transform Spectroscopy: 11th International Conference*, ed. J.A. de Haseth, American Institute of Physics, New York, AIP Conf. Proc., 430, 274–277 (1998).)

**Figure 11** Diffuse reflectance spectra of lip mucosa recorded by using different accessories. (a) Lip spectra of two different men measured against a white reflection standard by using a bifurcated fiber-optic probe. (b) Mean spectra from a group of 390 spectra from 133 patients (upper dotted trace) and from 219 spectra of one male (lower solid trace) obtained by using a diffuse reflectance accessory; the latter spectra were offset to give the same \(-\log R\) value at 9000 cm\(^{-1}\), deliberately shifted to zero (for the respective accessories, see Figure 12).

The accessories used were an optical fiber probe and a mirror based device. It can be seen that tissue optics play an important role in recording the in vivo spectra. In particular, the type and collection geometry of the accessory and source–detector separation are critical factors in the optimization of in vivo assays.
generated from a transducer, bonded to one face of a birefringent crystal, to produce a refractive index modulation. By tuning a range of radio frequencies it is possible to change the diffraction within the crystal, allowing a spectrum to be scanned at a special band pass. Other potent technology uses Fourier transform (FT) spectrometers, which are widely distributed and based mainly on a Michelson interferometer. Their primary information is coded in the interferogram which is Fourier-transformed to obtain the spectrum.\(^{27}\)

The detection electronics are an important part of the instrumentation. Usually for the NIR range, photodiodes of different semiconductor materials are used. Detectors manufactured by silicon technology can be photodiodes or extremely sensitive charge-coupled devices (CCD). Unfortunately, their cutoff is above 1050 nm, so that other materials for photon detection are preferred (e.g., InGaAs, Ge or InSb). The diodes from the latter material are generally used at \(-196 ^\circ C\). Nowadays, linear InGaAs arrays with up to 1024 pixels are available, often in combination with thermoelectric cooling by a Peltier device, allowing temperatures down to \(-30 ^\circ C\) and lower.

As thermal sources, tungsten–halogen lamps are used to provide the broad emission of electromagnetic radiation according to Planck’s law. Another option for radiation sources are light-emitting diodes (LEDs) and tunable lasers. With the limited tunability of the latter, the spectral range necessary for the applications discussed here can only be covered so far by a large number of different laser diodes. However, semiconductor diodes operating at about room temperature or below by thermoelectric cooling will be more accessible in the future. With the availability of such devices, other measurement techniques, as used in laser photo-acoustic spectroscopy, are possible with special probes for radiation delivery and detection.\(^{28}\)

Miniaturization and integration of optical and optoelectronic instruments is necessary to achieve portable, personal and hand-held instrumentation with minimal power consumption and high reliability, while maintaining low production costs. The question is whether low-level integration as seen, for example, with the availability of a four-channel filter based IR detector assembly is sufficient for the ambitious requirements of multi-wavelength in vivo measurements.\(^{29}\) For greater flexibility, mini- and microspectrometers are currently under development. Potent instrumentation is based on a concept which uses a LED array spectrometer.\(^{30}\) A linear LED array serves as the radiation source, coupled to a fixed grating monochromator for wavelength resolution and stability. The exit beam, with up to 32 different possible wavelengths in the SWNIR spectral range, delivers spectral pulses through an optical fiber, but extension to longer wavelengths has been promised.

High integration of an IR spectrometer based on silicon was also achieved, and the developments reached in microsystems for spectroscopic applications have recently been described.\(^{31}\)

Modern spectrometers often use optical fibers for the guidance of radiation, either employing single fibers or fiber bundles, sometimes with the aim of adapting the bundle cross-section to the spectrometer needs (a circular shape is optimal for focusing radiation into the fiber; the end could be shaped to suit the spectrometer entry slit). One affordable material useful in the NIR is an especially low-OH grade quartz with high transmission and the necessary range to reach into the mid-IR range, although other materials have also been in use.\(^{32}\) Additionally, measurement accessories for routine and process analysis can be constructed from such fibers. In Figure 12(a), a bifurcated, Y-shaped fiber-optic accessory is sketched. The fiber bundles, one for sample illumination and the other for radiation collection, usually contain fibers of about 0.2 mm diameter, and at the common end, all fibers can be arranged at random. Other configurations, for

\[ \text{Figure 12 Scheme of different accessories for a diffuse reflectance measurement. (a) Bifurcated fiber-optic probe. (b) Accessory based on a rotational ellipsoidal mirror (reflection optics).} \]
example concentric arrangements with or without a gap to select a particular optical pathlength and depth for tissue photons, are possible.\(^{(33)}\)

The optical properties of the fiber core and its cladding are critical for the radiation throughput of the fiber-optic cable. The so-called numerical aperture (NA) represents its radiation-gathering capability. The difference in the refractive indices of core and cladding defines the largest angle (\(\theta = \) acceptance half angle) for a cone of meridional rays, at which total reflection at the interface of both still takes place (\(n\) is the refractive index of the medium containing the cone vertex)

\[
NA = n \sin \theta = (n_{\text{core}}^2 - n_{\text{clad}}^2)^{1/2}
\]

For conventional measurements in transmittance or diffuse reflectance, accessories are also based on reflection optics.\(^{(26,34)}\) The arrangement favored by us consists of a rotational ellipsoidal mirror with one focus provided for the illuminated sample, whereas the second one is reserved for the detector (Figure 12b). The collection efficiency for diffusely reflected radiation is more than 50% for a Lambertian scatterer. The spectral signal-to-noise ratio for diffusely reflected radiation is more than 50% for a wavelength of 1.6 \(\mu\)m, the noise level in the skin spectra for the configuration described should be lower than 10\(^{-5}\) AU (absorbance units) to tackle the normal physiological glucose concentration level.\(^{(35)}\)

3.2.2 Chemometrics for Quantitative Spectrum Evaluation

For quantitative measurements the absorbance spectra of the sample are usually evaluated. Absorbance is the negative (decadic) logarithm of the transmittance spectrum (\(T\)), which provides the ratio of the transmitted against nonattenuated spectral radiant power. The absorbance values (\(A\)) are proportional to sample thickness and compound concentration (\(A = \varepsilon c b\), where \(\varepsilon\) is the absorptivity, \(c\) is the concentration, and \(b\) is the sample pathlength of the absorbing substance), as stated by the Lambert–Beer law. Whilst transmission spectroscopy has been used as a standard method to solve analytical problems since the beginning of IR spectroscopy, other techniques such as measuring diffuse reflectance (\(R\)) have become routine for the analysis of, for example, pharmaceutical substances, or the in vivo determination of the degree of oxygen saturation of hemoglobin in arterial blood in skin or other tissues. For linearization, as shown empirically by several authors, the use of \(-\log R\) values can provide a linear relationship between reflectance and concentration. A different, more rigorous approach is based on the theory derived by Kubelka and Munk (a description of this theory is given by Loyalka and Riggs\(^{(36)}\)), which is usually considered for quantitative measurements carried out in the visible spectral range, as well as in the mid-IR.

Generally, linear modeling of the spectra is the basis for their quantitative evaluation. A multicomponent analysis requires at least the same number of wavelengths as components. The classical multivariate approach for evaluating a sample spectrum containing the contributions from several compounds is to model this with all component reference spectra, which can be pure compound spectra or, in the case of substance interactions leading to spectral changes, the component spectra can be derived from mixture spectra of similar composition to that of the sample to be analyzed. The component concentration values for the sample are estimated by least-squares for equation systems, overdetermined in wavelengths. Spectral residuals can assist in outlier detection or elucidating modeling deficits.

For assays of biosamples, it is nearly impossible to have quantitative information on all components contributing to the spectrum. However, regressing concentrations against spectral data, the so-called soft modeling approach, works well. For statistical calibrations, it is essential that the calibration data span the range of variations that can influence the spectra of future unknown samples. There are a number of different multivariate calibration algorithms available. Often, calibration systems are ill-conditioned due to linear dependencies in the spectral data (so-called collinearity problem). For that reason, factor methods such as partial least-squares (PLS) are applied.\(^{(37)}\) A different approach, which is able to model nonlinearities explicitly, is the application of neural networks.\(^{(35,38)}\) As in other multivariate methods, calibration by “learning” is essential, but such an approach tends to be more susceptible to overfitting, and more difficult to handle and interpret than the linear approaches discussed before.

Special spectrum preprocessing has been presented, for example, to reach a temperature insensitive algorithm for in vitro glucose assays by using adapted Fourier filtering. The advantage gained from filtering is that an optimal PLS calibration model can be built from a smaller number of factors due to the elimination of spectral variance during the preprocessing step, but with nearly unchanged performance. In practice, it has been shown that a preselection of spectral intervals can significantly enhance the performance of calibration models. A first choice can be based on inspection of the so-called property correlation spectrum with the compound response spectrum, which is necessary a priori knowledge obtained from the calibration data.\(^{(39)}\) Correlations arising from other components can be manifested by calculating such a spectrum. This is
For calibration testing, the data are usually divided into two subsets, the first for calibration modeling and the second for prediction validation with independent data. This approach has the advantage that it does not rely on any statistical assumptions derived from the calibration stage. Another strategy is to have a modeling subset of samples (size $n - m$) and a validation subset of size $m$, but putting the data after validation back for repeat calibrations and selecting another subset of samples previously not implemented in the validation stage, until all samples have been used in the validation process. The root mean square error of prediction (RMSEP) is calculated from the prediction residual sum of squares. When the validation subset size is 1, this is called the “leave-one-out” strategy, which is a reasonable approach when only a limited number of samples is available for model training:

$$\text{RMSEP} = \sqrt{\frac{\sum (c_i - c_{i,\text{pred}}(R))^2}{M}}$$

where $c_i$ and $c_{i,\text{pred}}$ are the sample reference concentration values and the independently predicted values, respectively; $M$ is the total number of samples; and $R$ is, for example, the number of PLS factors used for the estimation of regression variables. Usually, the calibration model with the lowest RMSEP value is considered for future application, thus avoiding model overfitting.

The number of wavelengths optimally required for spectroscopic calibration is still a subject of intense debate. Especially for NIR spectrometry with filter instruments, the optimal design has been frequently discussed. In fact, once one uses as many variables as there are independent spectral constituents, the addition of further wavelengths should serve to reduce effects from noise. On the other hand, as more wavelengths are used, the probability of encountering additional spectral interferences increases. This progression eventually leads to a situation where the use of more variables starts to degrade the accuracy of the result. Special selection strategies have been followed in multiple linear regression (MLR) methods, which generally rely on a reduced number of spectral variables, see for example Draper and Smith.\(^{40}\) Step-wise regression is well known in statistical applications, and in a popular form, the forward or backward step-wise procedure, the algorithm calculates the linear regression between two sets of variables using least-squares, and selection is based on statistical confidence levels.

Recently, considerable effort has been made to evaluate procedures that identify spectral variables carrying useful information for the set-up of robust calibration models. A selection of papers dealing with these aspects, which consider search strategies such as genetic algorithms and simulated annealing or artificial neural network approaches, are given by McShane et al.\(^{41}\) We developed a rapid and reliable variable selection for statistical calibrations based on PLS regression vector choices, which has been tested for various calibration scenarios.\(^{42-44}\) As the optimum regression vector obtained from statistical calibrations contains the weights for the spectral variables needed for concentration prediction, spectral variables were chosen pairwise, providing the minima and neighbouring maxima of the regression vector, but in a ranking order decided by their coefficient weight size. The analytical performance of the calibration models, based on a consecutively increasing number of spectral variable pairs, is tested by cross-validation. The minimum RMSEP was taken for the selection of the optimum calibration model with a reduced number of variables under this scheme. For mid-IR studies with clinical calibrations for glucose in blood plasma or whole blood, only 10 variables were needed to reach the equivalent analytical performance obtained with broad spectrum evaluation.\(^{42}\) In contrast, the NIR studies with the same clinical blood plasma population showed that more than 20 variables were needed to reach the clinical acceptance level.\(^{43}\) The same procedure was successfully applied to data sets obtained within noninvasive assay development\(^{44}\) which will be discussed later.

Problems with statistical calibrations can occur if correlations exist between two compounds within the set of calibration samples, because this covariance can result in systematic prediction errors when the calibration model is applied to samples outside the calibration sample population. Therefore, the design of the calibration experiments is of critical importance. Extremely important for statistical calibration testing is the model validation, i.e. checking the performance for prediction using calibration-independent samples. As mentioned already, the number of samples needed for calibration, in particular for assays on natural specimens, can be large in order to model the range of variance factors to be expected, although strategies have been developed recently to reduce the calibration workload, including synthetically prepared samples of less complex composition than found for the natural specimens.\(^{45}\)

An appropriate experimental design is also necessary for sensitive in vivo calibrations when the analytical signals are comparable to the prevailing noise level or signal drifting. It is well known that the pickup of spurious drift
effects can significantly influence the results from multivariate statistical calibrations, especially when data were recorded under continuous monitoring conditions. In the past, our strategy for handling complex experiments was able to avoid temporal chance correlations. Surprisingly, positive results from calibrations were reached for single OGTTs using mid-IR spectra of the test person’s inner lip, obtained with the attenuated total reflection technique. However, by combining the calibration data from 2 days with several peaks and troughs in the blood glucose level, it became clear that the 1-day evaluations were dominated by spurious drift effects. If a priori knowledge on the compound signal features exists, this can be used for studying individual PLS factors and the regression vector shape to verify the physical basis of the calibration.

3.3 Tissue Spectroscopy

There are certain spectroscopic aspects to be discussed for the quantitative analysis of biomedical samples. Scattering in soft tissues is mainly due to discontinuities in the refractive index on the subcellular level. The mechanism of (elastic) radiation scattering from biological cells has recently been investigated by Mourant et al. who studied the scattering behavior of mammalian cells for wavelengths between 500 and 800 nm. Most of the scattering was caused by structures within the cells, but for larger wavelengths further investigations are needed.

Knowledge of the spatial distribution of photon-visit within tissue is important for quantitative diagnostics, since it defines the effective tissue volume which is probed by in vivo spectroscopy. For such a purpose, modeling of radiation transport in tissues is required. Estimation of the wavelength-dependent optical pathlength through tissue is required in order to quantify absolute analyte concentration values. For biological tissues we find anisotropic scattering, which is highly forward-directed. This is the reason why simple theories such as that derived by Kubelka and Munk are not valid, so that more sophisticated modeling is required, although under special conditions such a theory may be applicable. A detailed description of the theory can be found in a paper by Loyalka and Riggs.

The radiative transfer theory commonly preferred allows a treatment of radiation–tissue interaction, as only parameters of statistical relevance are used for optical tissue characterization; these are the average refractive index \( n \), the absorption coefficient \( \mu_a \), the scattering coefficient \( \mu_s \) (both in units of \( \text{cm}^{-1} \)), and the average scattering phase function \( S(\Theta) \). The absorption coefficient \( \mu_a \) equals the absorbance per unit length, \( 2.303 \epsilon_m C \), where \( \epsilon_m \) is the molar absorptivity and \( C \) is the molar concentration. The reduced scattering coefficient is defined as \( \mu_s' = (1 - g) \mu_s \), where the anisotropy parameter \( g \) is the mean cosine of the scattering angle \( \Theta \). More complex cases than found for isotropic media have been considered, for example, such as layered structures to model skin. A comprehensive summary of relevant terms in tissue optics was given by Patterson et al. In order to explain the NIR spectra and for a better understanding of radiation transport, e.g. by means of maximum penetration depths and integral photon pathlengths, Monte Carlo simulations of the “photon random walk” through tissue can be carried out. This refers to numerical calculations based on random sampling from appropriate probability distributions. With these tools, it is also possible to model the effects of physiological factors and different analytes for certain measurement scenarios, provided that their effects on the absorption and scattering properties of the tissue are known.

The in vivo spectroscopy can be described from a practical point of view. In Figure 13, the diffuse reflectance spectra of lean muscle tissue are presented, recorded at different layer thicknesses by using a mirror optics based accessory. The intensities at lower wavenumbers are displayed, which are more favorable than found for a fiber-optic probe. The backscattered radiation intensity is low, so it is necessary to have extremely accurate and reproducible measurements, in addition to a high spectral signal-to-noise ratio. For SWNIR applications, also based on Monte Carlo simulations, a modified Lambert–Beer law can be expressed as \( A = (\epsilon C Db) + G \), where \( D \) is the differential pathlength factor due to photon diffusion, and \( G \) is an additive term due to scattering losses. This interpretation is valid for the reflectance data from Figure 13, when transformed into absorbance equivalent values. Additional losses from scattering, which are nearly

![Figure 13](image-url) Reflectance spectra of different layers of lean muscle tissue backed by a brass plate (from bottom: layer thicknesses 1.6, 1.0, and 0.5 mm) and measured by means of the accessory based on reflection optics.
constant over a wide spectral range, are accompanied by an increase in sample layer depth.

3.3.1 Skin Structure and Chemistry

Skin is composed of three layers: the epidermis, the dermis and the subcutaneous-tissue layer, which includes adipose fat cells. It contains other elements such as hair and different glands and structures like blood vessels, lymphatics and nerves. Epidermal thickness can vary between 60 and 100 µm, but it is remarkably constant over the body, apart from special areas with a thick stratum corneum layer. The thickness of the dermis, which is connective tissue composed of fibrous proteins (predominantly collagen and elastin fibers) and proteoglycans, can vary tremendously, depending on the body location. The heterogeneity of body tissues is illustrated in Figure 14, which shows a cross-section through the upper part of inner lip skin. The cornified, thin keratinized surface layer of normal skin epidermis, the stratum corneum, is missing here. A thorough review of the anatomy of the skin is beyond the scope of this article, but a few details relevant to in vivo spectroscopy are given.

The skin can be considered as the largest body organ, and it has different functions, such as providing a protective barrier. For a greater part, this is achieved by the stratum corneum, a horny layer which evolves from a dense population of actively dividing epidermal cells. For mucous tissues such as oral mucosa, the stratum corneum does not exist, which can be advantageous in diffuse reflectance measurements. Other skin functions include the regulation of body temperature and water content. A considerable amount of body water is accumulated in the skin, and a large proportion is found interstitially. The ability of skin to act as a reservoir is observed under various pathological conditions, with prominent uptake, for example, in kidney insufficiency and obesity, whereas dehydration is seen, for example, in diabetes insipidus. Surgical skin specimens of fat-free skin show a typical average water content of 72%. The epidermal water content is lower due to the horny layer. These figures vary because of substantial variations in water content over the surface and between different types of skin.

In addition to collagen, hyaluronic acid is an important component. The actual location of water and the amounts associated with various components such as collagen and other proteins is not clear, but water has been seen as an integral component of collagen structure, being essential for maintaining the fibrillar collagen structure. Swelling of the polymer network by water is observable. The quantity and nature of proteins and mucopolysaccharides very profoundly affect the extent of water uptake. Variations in water content with age are well-known. Differences due to gender and diet have also been reported.

Apart from the structural variability, changes in vasodilation and vascular permeability, the concentration of hemoglobin in blood and its oxygenation status, as well as pigmentation from melanin, carotenoids, etc. influence the optical characteristics of cutaneous tissue, especially in the visible and SWNIR spectral ranges. As water is the main constituent in soft tissue, the NIR absorption spectrum is dominated by this compound and its variations. Additionally, scattering changes are dependent on the tissue water content, because the differences in the refractive index discontinuities at the subcellular level are affected.

The networks of blood vessels within the skin are shown schematically in Figure 14(b). Capillary loops extend almost to the surface of the skin. Vascular patterns in skin and their variations have been discussed recently. By changing blood flow, thermoregulation can be controlled. There is certainly a temperature gradient along the skin depth, affected by the blood flow within the vasculature, which influences the spectroscopic variations seen during in vivo monitoring.

Other variations are a result of skin irritation, photobiological processes and/or skin diseases, which also affect the structural and chemical characteristics. Exposure to a diversity of chemicals in soaps, moisturizers and...
detergents certainly affects the skin and may even cause inflammation. These variations can also be followed by skin spectroscopy.

3.3.2 Skin Spectroscopy

The effects from different accessory geometries on skin spectra are discussed in this section. In Figure 11, spectra from the inner lip obtained with a fiber probe and a diffuse reflection (DR) mirror-based accessory are shown. For these cases, a reasonable match in refractive indices is given for the interface from tissue and the contacting optical material, which fortunately leads to negligible Fresnel reflection, which would otherwise cause unwanted perturbations if larger refractive index differences between the layers were present. This would be especially undesirable as this radiation fraction carries no analytical information. When we look at the spectral features below 6000 cm\(^{-1}\), subtle differences can be detected. In the spectrum of skin from a man, recorded with the DR accessory, a broad single band attributed to water is seen. The top spectrum in Figure 11(b), which is an average spectrum from a large population of men and women, indicates a weak doublet, whereas the spectral features obtained with the fiber-optic accessory clearly indicate the probing of subcutaneous fatty tissue.

In Figure 15, the diffuse reflectance spectra of muscle and fatty tissue are shown, and these support this view. For the phospholipid lecithin, a special lipid representative, a spectrum is shown in Figure 5. For completeness, further lipid classes are mentioned: fatty acids and their derivatives, triglycerides and sterols. In Figure 16 the variability in lip spectroscopy is illustrated. In Figure 16(a), the spectral differences between consecutively measured lip spectra of a man are shown, also indicating changes in the tissue water. Figure 16(b) gives the difference spectrum between the average inner lip spectra obtained from women and men, respectively. In addition to the difference in water content, a larger contribution to the spectrum from fatty tissue of the oral mucosa in women can be seen.

The effect of different contact pressures on the lip spectrum is illustrated in Figure 17. The spectra were again recorded by using the DR accessory, and by applying low and heavy pressure during measurement. The resulting difference spectrum shows spectral features similar to a cuvette spectrum of blood plasma.

In Figure 18 the influence of the stratum corneum on the diffuse reflectance skin spectra is shown. In Figure 18(a), the spectra of a finger tip, recorded by a fiber probe and a mirror-based DR accessory (see Figure 12), are given. Whereas the scattering top layer has little effect on the skin spectra (Figure 18b), there is a tremendous difference seen compared with the oral mucosa spectrum (cf. Figure 17). With a thicker stratum corneum layer, as seen for thumb skin compared with that of the outer lip, the spectral features of keratin become evident below 6000 cm\(^{-1}\). These effects are even more intense for spectra of the heel or thumb tissue when measured through the

finger nail. For completeness the keratin spectrum of hair is also shown in Figure 18(c).

The variability within skin tissue spectroscopy is summarized in Figure 19. Figure 19(a) shows the spectral standard deviation, as obtained by using the DR accessory with repeated repositioning of the probe to the inner lip, for a multiperson and a single-person experiment (the corresponding mean lip spectra are shown in Figure 11b), whereas in Figure 19(b) the standard deviation data are presented for a fiber-optic probe, measuring inner lip and thumb spectra with and without repositioning of the probe (for the corresponding tissue spectra, see Figure 18b). There are significant reductions in spectral variance with a fixed spectroscopic probe.

overlap) with respect to the assay performance for glucose has been investigated recently.\(^{14,50}\) For such a purpose, a large population of human plasma samples from a hospital was analyzed by clinical enzymatic methods. The spectra were recorded by using either a 10-mm or 1-mm quartz transmission cell. Respective spectral data for calibration ranged from 11 000 to 7600 cm\(^{-1}\) (SWNIR) or from intervals below 6800 cm\(^{-1}\). By using the optimum calibration model, the NIR spectra recorded with the 1-mm cell produced a relative standard deviation of 7.8\% (based on the mean glucose concentration of the samples), whereas significantly worse performance was achieved using SWNIR data with a respective value of 23\%. Handicaps of the SWNIR region are the weaker absorption coefficients of the plasma components and the much broader absorption bands, leading to a poorer selectivity for the calibration compared to other spectral ranges. For the long-wave NIR with data below 6800 cm\(^{-1}\), exclusion of spectral intervals with the largest variances from water was necessary to reach the calibration results mentioned above.

Generally, the measurement conditions for the in vitro analysis of aqueous biofluids can be kept much more constant with regard to temperature, sample homogeneity and optical pathlength than for in vivo measurements, where many physiological variables are to be considered for skin tissue: peripheral blood perfusion with shunting or other circulatory variations, an inhomogeneous distribution superimposed on an unknown coarse glucose gradient, and a temperature profile with additional fluctuations in mean body temperature. In addition, the thickness and anatomic structure of the skin can vary tremendously. Despite these variations, the spectrometric assay performance for in vitro samples allows some extrapolation for in vivo measurements.

3.4.1 Integral Tissue Measurements

The most promising results have been obtained for individual patients where the measurement conditions have been investigated in greater detail. In vivo experiments can be performed on a subject, e.g. under fasting conditions, oral glucose or meal tolerance tests or glucose clamp experiments with constant blood glucose levels. Parallel to this, reliable reference data for the calibration must also be obtained from invasive blood tests, either by puncture of the skin or by using, for example, syringes for taking venous blood. It is advisable that the data gathering on the time-dependent blood glucose profile are dense enough to allow data interpolation to reconstruct the temporal dependency needed for mean tissue glucose modeling. There is certainly a great deficit for modeling when only single blood glucose measurements with large time gaps are available, which do not permit any estimates on mean tissue glucose.

As discussed above, the blood fraction in skin is quite variable, so skin hyperemization is advisable to reach optimum conditions with a high blood content and largest blood flow for reducing gradients in the vascular system. The blood volume could be monitored by diffuse reflectance spectroscopy in the visible spectral range by determining the hemoglobin concentration. When oral mucosa is the preferred tissue for in vivo monitoring, cleaning of the oral cavity is important in order to avoid spurious results caused by the presence of food residues.

It is a prerequisite for a working calibration that the concentration variance in the calibration data set is large enough to allow for the calculation of satisfying
calibration models. The signal-to-noise ratio must be sufficiently high to enable extraction of meaningful information from the spectral data.

Various calibration experiments with an individual person, as well as with 133 patients, were carried out by us (see also Heise et al. (44) and references cited therein). NIR spectra of the human inner lip were measured using the specially optimized accessory for diffuse reflectance measurements, attached to an FT spectrometer, to allow skin spectra with a noise level of about $10^{-5}$ AU. Measurement time was about 1 min to accumulate 1200 single-sided interferograms equivalent to a spectral resolution of 32 cm$^{-1}$ after Fourier transformation. This is the maximum measurement time usually tolerated by patients. PLS multivariate calibration with spectral variable selection was applied for regression of the spectral data between 9000 and 5500 cm$^{-1}$. In Figure 20 the design of two different calibration experiments is sketched with data gathering over 2 days and over 2 weeks, respectively. For compressed presentation the time gaps between the different daily sessions were deliberately reduced.

In the 2-day calibration experiment, a nonstandard OGTT was used and a time delay of the glucose concentration profile of 10 min for calculating the reference concentration data was applied (optimized by variation testing). The optimum calibration models were obtained with “leave-one-out” cross-validation. In Figure 21(a) the RMSEP results from different PLS models based on 26 selected spectral variables are shown, and an optimum calibration model from 132 calibration samples, logarithmized lip reflectance spectra with corresponding reference blood glucose concentrations, is obtained with 16 PLS factors. On the other hand, a least-squares solution of the regression coefficients gives about the same performance. The calibration model can predict glucose concentrations with an RMSEP of 36 mg dL$^{-1}$. The robustness of the calibration model is also underlined by the fact that cross-validation with packages of five standards shows only an insignificant deterioration compared to the “leave-one-out” strategy. The prediction results are plotted in a scatter diagram for acceptance testing. Routinely, the Clarke error grid has been used for data presentation, (51) but we prefer a straightforward presentation similar to that proposed by Koschinsky et al. (52) Such a presentation using logarithmic scales is given in Figure 21(b), where the confidence interval for a 30% relative standard deviation is marked by dashed lines (for self-monitoring devices a value of 15% has been claimed, but this is not always reached).

The 2-week experiment led to an optimum RMSEP value of 47 mg dL$^{-1}$, which is significantly higher than the results from the 2-day calibration data due to the larger variability in the spectral data compared to the 2-day test. However, such a testing scenario is more realistic for diabetic patients performing everyday blood glucose monitoring. The performance is illustrated for a sequence of days in Figure 20(b). There are some situations where the scatter of prediction results is unacceptably large. Further investigations are necessary to study the major factors affecting the prediction performance of such a spectroscopic assay. In this context, perturbations from other compounds, such as from medications, must also be investigated in the future.

A better understanding of NIR in vivo spectroscopy of integral body tissue, in particular the skin, is still...
needed to learn more about biosystem complexity, but the same applies to other body samples, such as the aqueous humor. It also means that standardization of the measurement is vital, but an even more sophisticated data reduction scheme, including outlier detection, will be necessary rather than the simple calibration approaches chosen so far. With the increasing capabilities of NIR spectrometers, and computers handling more data with refined algorithms, the time when a noninvasive approach for metabolite determination could be utilized for the patient at home or in the hospital is not out of reach.

3.4.2 Pulsatile Spectroscopy

Integral tissue probing faces many unknown physiological variables. Further development of noninvasive assay technology can be based on fast subsecond NIR spectroscopic measurements, allowing the probing of parts of the intravascular fluid space, since its arterial volume is modulated by the heart beat. It is the situation as found for pulse oximetry, by which the degree of HbSO₂ can be determined. Spectrum changes can be monitored synchronously to the cardiac cycle. During systole the capillary blood volume is increased, which leads to a higher absorption of IR radiation due to water, hemoglobin and other blood constituents; the situation is opposite during diastole. However, since the arterial blood constitutes a small and unknown fraction of the tissue, the alternating signal is only a minor fraction compared to the total tissue water, which also varies with the physiological state of the microvasculature and the tissue texture. Owing to limitations in signal-to-noise ratio, such a measurement principle, although proposed in patents, has not yet been applied in practice for metabolite measurements.

Preliminary results of time-resolved measurements on human oral mucosa were recently presented using diffuse reflectance spectroscopy. The first individual lip spectra obtained with fast measurements are shown in Figure 22(a). These are difference spectra smoothed for noise reduction, as calculated versus the first measured spectrum of the data set, after application of a polynomial baseline fitted to predefined spectral intervals which are located in the spectrum minima. It clearly illustrates the intensity fluctuations caused by changes in the arterial blood compartment associated with the cardiac cycle. Each Fourier analysis of the time-dependent logarithmized intensities, assigned to the individual spectral variables, provided the spectral Fourier amplitudes for each frequency component. Considering a three-dimensional diagram with spectral wavenumber variables, frequency components in hertz and pulsatile amplitudes as ordinates, the pulsatile spectrum evolves along the heart beat frequency. This has no static component, originating from the aqueous unmodulated compartments of the skin tissue. The pulsatile spectrum, showing only component changes with pulse, is a type of difference spectrum (see Figure 22b), and is similar to the water absorbance spectrum recorded with a transmission cell of 0.5-mm pathlength. The water absorbance alterations due to the cardiac blood pressure changes are about 20 mAU for the water band at 6900 cm⁻¹. This is equivalent to a water layer of 15-µm thickness, which is about a factor of 50 smaller than obtained for the integrating measurements discussed above. It is noteworthy that the ratio of the maximum amplitudes of the water combination band at 5200 cm⁻¹ and of the overtone band at 6900 cm⁻¹ is much smaller for the pulsatile spectrum than for the
Figure 22 (a) Fast measurements of inner lip spectra of a single person shown as differences versus the first measured lip spectrum after spectral smoothing. (b) Fourier amplitudes (upper trace) illustrate the relative pulsatile spectral components in the near-IR diffuse reflectance spectra of human oral mucosa due to cardiac-modulated blood volume variations (for each spectral variable the Fourier amplitude coefficients were averaged around the heart beat frequency within a frequency interval of 0.06 Hz); for comparison the absorbance spectrum of water as measured in a 0.5-mm cell is given below (lower trace, right ordinate scale). (Reproduced by permission of Walter De Gruyter from H.M. Heise, A. Bittner, R. Marbach, ‘Near-infrared Reflectance Spectroscopy for Non-invasive Monitoring of Metabolites’, Clin. Chem. Lab. Med., 38, 137–145 (2000).)

The complexity of lip spectra can best be evaluated by using a principal component analysis (PCA). For this, the matrix of calibration spectra is decomposed to give factor spectra which provide a system of orthogonal basis vectors to span the spectral space from the calibration data. The vectors can be derived from a singular value decomposition of the matrix, defined by maximizing the variance subsequently in the remaining subspace. Such an analysis was carried out for the individual lip spectra measured within 350 ms and recorded for the lapse of 2 min, as well as for the lip spectra obtained within the one-person, 2-week, calibration experiment. The first ten factor spectra, normalized to the same minimum–maximum distance of their vector components, are presented in Figure 23. As the first

Figure 23 Factor spectra from a PCA of the logarithmized inner lip spectra of a single person recorded during a 2-week testing experiment (solid lines) and of logarithmized inner lip spectra from a different person obtained during 1 min (sampling frequency: two spectra recorded per second; dashed lines). (a) The minimum–maximum normalized loading spectra of the first five principal components. (b) The additional five factor spectra related to further decreasing singular values of the original calibration spectra matrix.
five vectors (without regard to their sign) show great similarity due to the dominating variance contributions from tissue water, the other factor spectra from the 1-min integrating inner lip measurements possibly demonstrate that different sampling tissue sites due to repositioning over 2 weeks increase the complexity of the data. As a consequence, calibration modeling with a greater number of factors is required for efficient glucose assays using this approach than would be necessary using pulse spectrometry. Additional complexity is given for any of the optical approaches probing a certain skin volume integrally, because it is important to know the relationship between glucose concentrations in blood and interstitial and intracellular compartments.

4 REVIEW ON CURRENT ALTERNATIVE TECHNOLOGIES

4.1 Fluorescence Spectroscopy

In the past, fluorescence had been investigated as an implantable glucose sensing approach. A similar strategy was followed by Lakowicz and Maliwal who investigated lifetime-based sensing using fluorescence resonance energy transfer based on the reversible association of concanavalin A with dextran. A slightly variant method was previously presented based on the luminescence decay time of a long lifetime metal–ligand complex. An attempt has been made to develop a transdermal methodology using sensing patches implanted below the skin which show a fluorescence change correlated to the tissue glucose concentration ("quasi-noninvasive approach"). A NIR assay based on long-wavelength dyes has recently been evaluated, although this technological advance has not yet been applied to physiological fluids.

4.2 Polarimetry

The monosaccharide D-glucose exists in two stereoisomers (α-D-glucose and β-D-glucose). Owing to their chirality, these substances are optically active, i.e. they give rise to an opposite optical rotation of linearly polarized electromagnetic radiation. In aqueous solution, this effect, which is proportional to concentration and sample pathlength, can be conveniently measured, because the concentrations of the α- and the β-form of glucose are not equally balanced. Quantitative measurements have been carried out by polarimetry for a long time, since optical activity was first observed in the beginning of the last century by Arago, Biot and Seebeck. However, the interaction of physiological glucose with electromagnetic radiation allows the determination of such low concentrations by using microdegree polarimetry.

This technique was successfully applied for cell culture media. As the skin shows significant radiation scattering, such a measurement is extremely difficult due to depolarization of the probing light. Therefore, this methodology has been suggested for measuring the glucose concentration of the aqueous humor within the anterior chamber of the eye. Glucose can be measured when a beam of polarized light passes laterally through the eye. The polarimeter used a Faraday modulator to generate the polarization modulation of the incident laser beam before it reached the sample. A digital closed-loop approach using a Faraday compensator and an analyzer for nulling the optical rotation due to glucose increased the robustness of the measurement apparatus. A recent paper gives results for a multispectral in vitro method for compensating effects from albumin and preliminary single wavelength in vivo results supporting the use of such a technique to be employed for a noninvasive glucose assay. A device for coupling light through the anterior chamber of the eye has also been presented. Chou et al. used an optical heterodyne polarimetric approach for in vitro samples and illustrated its use for glucose detection by using a rabbit’s eye. Problems reported so far concern corneal birefringence and eye motion. There was a 30-min time delay between the concentration profiles of the humor and blood glucose. Another topic of interest is the patient’s acceptance of such an eye measurement device, apart from the fact that such a time delay results in a loss in glucose regulation within a closed-loop feedback system.

4.3 Scattering Approaches

Apart from absorption measurements, a different approach was evaluated by several groups. There are four different effects from dissolving glucose in an aqueous scattering biosystem: two effects influence the absorption coefficient due to an increase in intrinsic glucose absorption and to water displacement, and the latter is not selective enough for in vivo monitoring. Two further effects are noticeable: changes in the refractive index and the scattering coefficient, which has been mentioned earlier. Utilization of the latter effect led to the development of portable instrumentation with two optical sensor heads, each containing four LEDs of different wavelengths in the visible and SWNIR range, and six photodetectors were located at different millimeter distances. The monitoring of tissue glucose concentration was carried out during several glucose clamp experiments. The general variability, i.e. glucose-independent changes in scattering of skin, was also investigated. Specificity is the greatest concern, because many other effects unrelated to glucose can influence the scattering signal. Some significant influencing factors have been discussed in section 3.3.1. On the
other hand, the instrumentation is attractive as it is simple and affordable, and allows continuous monitoring.

4.4 Raman Spectroscopy

A complementary technique to IR is Raman spectroscopy: a transition between vibrational energy levels is also induced, but this involved radiation scattering by the molecules. Unlike IR spectroscopy, however, monochromatic laser excitation is used. One great advantage is that the Raman spectrum of water is weak, which is certainly in contrast to mid-IR spectroscopy. Much effort has recently been placed on a multicomponent assay using NIR Raman spectroscopy, emphasizing the splendid potential of vibrational spectroscopy for its suitability in clinical chemistry assays due to its selectivity based on fingerprint-like fundamental vibration spectra. In contrast to skin, analysis of components in the aqueous ocular humor may well be achieved by using Raman spectroscopy, although laser excitation power is a primary concern. For avoiding a large background fluorescence, NIR laser excitation is usually considered for the Raman spectrum recording, although a tremendous tradeoff is seen due to longer wavelength excitation, compared to excitation with lasers in the visible range. Stimulated Raman spectroscopy using a pump and a probe laser for the same biofluid has also been proposed, and theoretical studies on the sensitivity have been presented. More details on Raman spectroscopic approaches can be found in a review on noninvasive glucose measurements.

So far, in vivo experiments still present many problems.

CONCLUDING REMARKS

There are further spectroscopic techniques, the potential of which has still to be assessed. Photoacoustic spectroscopy within the NIR range has been mentioned in section 3.1. Another challenging technique is emission spectroscopy in the mid-IR produced by utilizing temperature gradients in the skin, and this is currently under intensive testing. American companies such as Biocontrol Technology Inc. or Futrex Inc., using NIR absorption spectroscopy, have frequently been in the headlines, but their photons technology has still to achieve levels needed to meet the expectations in noninvasive blood glucose testing. Their technology has yet to demonstrate the reliability required by the United States Federal Drug Agency (USFDA) to market such devices in the United States. The fluctuations in the industrial diagnostic instrument area are large, where many different systems are currently under design and testing, driven by the plethora of patents issued in this field of noninvasive testing. A snapshot of current company activities can be found in a recent article by Diller, which is incomplete, as her research did not cover the European and Japanese activities!

One necessary trend is that the analytical instruments have to move closer to the patient, which certainly culminates in the development of miniature noninvasive measurement devices for blood glucose self-monitoring. The optical approach, in particular in vivo absorption NIR spectroscopy using diffuse reflectance of skin tissue, is promising for the future. In the meantime, implanted biosensors or microdialysis probes, in combination with glucose biosensors, are competing techniques, but face different problems within in vivo assays. These can be avoided by optical techniques, ranked highly owing to their noninvasive analytical methodology.

ACKNOWLEDGMENTS

INFRARED SPECTROSCOPY IN CLINICAL AND DIAGNOSTIC ANALYSIS

Infrared Spectroscopy in Clinical and Diagnostic Analysis

R. Anthony Shaw and Henry H. Mantsch
Institute for Biodiagnostics, National Research Council of Canada, Winnipeg, Canada

1 Introduction

The infrared spectrum of a mixture serves as the basis to quantitate its constituents, and a number of common clinical chemistry tests have proven to be feasible using this approach. This article reviews the infrared spectroscopy-based analytical methods that have been developed for consideration as clinical assays, including serum analysis, urine analysis, amniotic fluid assays for the estimation of fetal lung maturity, and others. Because of the widespread interest in the potential for in vivo measurement of blood glucose using near-infrared spectroscopy, a separate section is devoted to the analysis of glucose in whole blood.

A related technique uses the infrared spectrum of biomedical specimens directly as a diagnostic tool. For example, the spectra of serum and of synovial fluid have proven to be useful in the diagnosis of metabolic disorders and arthritis, respectively, without explicitly recovering their chemical composition from the spectra. Rather, characteristic spectral features and patterns have been identified as the basis to distinguish spectra corresponding to healthy patients from those corresponding to diseased patients. These applications are reviewed here.

Issues such as ease of use, speed, reliability, sample size, and calibration stability all play important roles in governing the practical acceptability of infrared spectroscopy-based analytical methods. To provide a framework to illustrate these issues, descriptions are included for the various procedures that have been explored to wed successfully infrared spectroscopy to clinical chemistry.

1 INTRODUCTION

Infrared (IR) spectroscopy has emerged in recent years as the analytical method of choice in an enormous variety of applications. What brought about this revolution? The clearest advantage is that no specific reagents are required. Automated, repetitive analyses can therefore be carried out at very low cost. The appeal of these factors has spurred the development of a new generation of analytical IR spectrometers that combine high acquisition speed with superb spectral sensitivity. Powerful chemometric algorithms and software packages have emerged in parallel with the new hardware, and new applications emerge continually.

Rather than relying upon reagents to promote color reactions, IR-based analysis is founded upon the spectrum of IR colors characteristic of the analyte itself. If a particular component provides an IR absorption spectrum, and its concentration is high enough that the spectrum contributes meaningfully to the IR absorption profile, then it may, in principle, be quantified by using IR spectroscopy. Although the requirement that the
component exhibits an IR absorption spectrum rules out the quantitation of simple ions, a number of very common clinical analytical tests may, in principle, be carried out using IR spectroscopy.

This article begins by comparing and contrasting mid-infrared (MIR) and near-infrared (NIR) spectroscopy in the context of analytical applications. The second section describes the general approach to generating an IR-based quantitation method. Although Beer’s law generally holds true for common analytes in biological fluids, it is very unusual to find a single absorption that can be used as the basis to quantify any single component in real-life samples. Analytical methods that are based upon IR spectroscopy must nearly always be calibrated by reference to accepted clinical analyses, using multiple-wavelength linear regression or other full-spectrum methods.

The function of the clinical chemistry laboratory is to perform quantitative and qualitative analyses on body fluids such as serum, blood, urine, and spinal fluid, as well as other materials such as tissue, calculi, and feces. The main body of this article describes IR-based methods to carry out some of the most common clinical analytical tests, specifically those involving serum, whole blood, and urine. Fluids that are less commonly assayed (e.g. saliva and amniotic fluid) are also discussed separately. NIR spectroscopy has achieved some notoriety in the clinical chemistry arena because of the early promise that it might serve as the basis for a noninvasive blood glucose test. Some relevant in vitro studies are surveyed briefly here. The article closes with a discussion of novel approaches to derive diagnosis directly, without explicit quantitative analysis, from the spectra of biological fluids.

2 INFRARED SPECTROSCOPY OF BIOLOGICAL FLUIDS

The IR spectral region ranges from the red end of the visible spectrum at 780 nm (12 820 cm⁻¹) to the onset of the microwave region at a wavelength of 1 mm (10 cm⁻¹). Traditionally, this range is further subdivided into the near-infrared (NIR), mid-infrared (MIR), and far-infrared (FIR). The MIR region covers the range 400–4000 cm⁻¹, and is the region most familiar to the organic chemist as providing a “fingerprint” characteristic of molecular species. It is this region that includes the rich absorption profiles for native serum in the MIR and NIR spectral regions. Although some of the stronger solute absorptions do emerge in the MIR spectra, water clearly dominates the overall appearance. The NIR spectra are

![Figure 1](image-url)
apparently devoid of any absorptions other than those of water.

MIR and NIR spectroscopies in fact offer quite different, complementary, approaches to analysis. The richness of the MIR spectrum makes it instinctively appealing as the method of choice for analytical work, however NIR has practical benefits such as convenience in sample handling and the fact that the sample cells do not require specialized materials. Whereas MIR spectroscopy of aqueous specimens typically requires optical path lengths of the order of microns, NIR transmission spectra are generally collected using path lengths of 0.5 mm or greater. The question of whether to use NIR or MIR spectroscopy for analytical purposes then translates to the question of whether the additional effort generally required to acquire MIR spectra is compensated by other possible benefits such as greater analytical accuracy or smaller sample volume.

2.1 Mid-infrared Attenuated Total Reflectance Spectroscopy

Attenuated total reflectance (ATR) spectroscopy provides an alternative means to measure absorption spectra by using the experimental arrangement illustrated in Figure 3. The clearest advantage of this method is that it provides a means to measure MIR spectra for strongly absorbing aqueous solutions, without the inconvenience and imprecision involved in working at very short path lengths that are required for transmission spectroscopy. Rather than transmitting IR radiation through the specimen, the liquid sample is placed in contact with the ATR optical element. The refractive index of the element (typically zinc selenide) is high enough that the IR beam propagating through it undergoes several internal reflections as it travels through the crystal. A background spectrum is first measured with no sample in the cell. The sample is then placed in contact with the crystal. The internally reflected beam effectively penetrates the sample to depths of 0.5–2 \( \mu \text{m} \) and hence is attenuated at wavelengths corresponding to sample absorptions. Ratioing the resulting single-beam spectrum against the background spectrum results in a spectrum that is nearly identical to the absorption spectrum, differing only by virtue of the wavelength dependence of the penetration depth.

2.2 Mid-infrared Spectroscopy of Dried Films

This approach fineses the difficulties associated with strong water absorptions by simply eliminating water from the specimen. Typically 5–50 \( \mu \text{L} \) of liquid is spread on a suitable substrate and allowed to dry, and a transmission spectrum is acquired for the resulting film. In addition to eliminating the spectral interference of water,
this approach can provide inherently better spectral resolution by virtue of eliminating the water/solute interactions. A representative spectrum of a dry serum film is illustrated in Figure 4.

2.3 Near-infrared Spectroscopy

Although the NIR is defined as encompassing the 780–2500 nm spectral range, it is convenient to subdivide further this span into natural subregions. The 2000–2500 nm range includes the most intense absorptions and thus is the region most commonly exploited for analytical purposes. Absorptions in this region correspond to “combination bands”, combining X–H (where X = C, N, O) stretches with other fundamental vibrations, whereas practically all of the higher energy transitions correspond to vibrational first (1400–1800 nm), second (950–1250 nm), and third overtones (Table 1).

The diversity of transitions in the NIR region has interesting practical consequences. For aqueous solutions, the 2000–2500 nm region is best explored by using a transmission cell with an optical path length of 0.5–2.5 mm. The optimal path length to observe the first overtone transitions is longer – of the order of 5–10 mm – whereas observation of the second overtones requires a path length of several centimeters. Where sample volume is a consideration, a relatively short path length is a necessity and the combination region is therefore preferred. Another outgrowth of this trend is that tissue is relatively transparent at shorter NIR wavelengths. A key consideration in the search for in vivo analytical methods (e.g. blood glucose) is therefore preferred. Another outgrowth of this trend is that tissue is relatively transparent at shorter NIR wavelengths. A key consideration in the search for in vivo analytical methods (e.g. blood glucose) is therefore to arrange the experiment such that the effective optical path length is optimized for the appropriate analyte NIR absorption features. A proposed in vivo method based upon the combination bands will require a short effective path length, whereas a method that monitors second overtone absorptions would require a much longer one.

3 CALIBRATION METHODS

In the vast majority of cases, IR-based analytical methods are developed via calibration to accepted reference analyses. The term “calibration” therefore describes the derivation of a model with which to recover quantitative analytical information from the IR spectra. Although this step is obviously a trivial one for very simple one- or two-component systems, more complex mixtures require a more sophisticated approach.

The general procedure is the same regardless of the details of the process. The first stage is to accumulate both IR spectra and reference assays for a set of appropriate clinical specimens. Ideally, this set of calibration samples should span the range of concentrations expected both for the analyte of interest and for any interfering species (i.e. any IR absorber other than the target compound). Separate calibration models are then developed for each of the target analytes. Finally, each of the calibration models is validated by comparing IR-predicted levels to the reference levels determined for an independent set of test specimens. An outline of the model development process is presented in Table 2.

Where IR methods are sought for more than one species, the calibration/validation procedure is carried out independently for each analyte.
principal component regression (PCR), and partial least squares (PLS).

3.1 Multiple-wavelength Linear Regression

This approach is simply an extension of Beer’s law to include multiple wavelengths. The need for several wavelengths is dictated by the inherent richness of the IR spectra – it is generally difficult or impossible to find a single absorption corresponding to a particular analyte that is not overlapped by the absorptions of at least one other constituent. The Beer’s law relationship shown in Equation (1):

\[ A = \varepsilon c L \]  

is therefore replaced by the more general form shown in Equation (2):

\[ A = \sum \varepsilon_i c_i L \]  

where \( A \) is the absorbance, \( \varepsilon_i \) is the molar absorptivity of the \( i \)th constituent, \( c_i \) is the concentration of the \( i \)th constituent, and \( L \) is the optical path length. The expression relating the concentration to IR absorption intensities then takes the form of Equation (3):

\[ c_i = K_{c_i} + K_{1i}A(\lambda_1) + K_{2i}A(\lambda_2) + \cdots + K_{Ni}A(\lambda_N) \]  

where \( K_{Ni} \) are the calibration coefficients for the \( i \)th constituent, and \( \lambda_N \) are the corresponding analytical wavelengths.

This approach is most readily applied when the spectra show dominant absorptions corresponding to the analyte of interest. This proved to be the case in the NIR analysis of urine urea. Figure 5 compares the spectra of five representative urine specimens in the NIR region of 2050–2500 nm, together with the spectra of five aqueous urea solutions spanning the concentration range 30–230 mmol L\(^{-1}\). In this instance the spectral features due to urea clearly dominate the urine spectra, and it is not surprising that a single-wavelength Beer’s law relationship provided quite good accuracy in extracting the urea concentrations. In particular, the intensity of the feature at 2152 nm proved sufficient to recover urea concentrations with a standard error of 20 mmol L\(^{-1}\) over the physiological concentration range of 100–500 mmol L\(^{-1}\). The accuracy was improved, however, by including additional terms as shown in Equation (4):

\[ C(\text{urea}) = -10 + 68 \frac{A(2152 \text{ nm})}{A(1194 \text{ nm})} + 1.3 \times 10^5 A(1724 \text{ nm}) \]  

There are two new wavelengths in this model. The first, at 1194 nm, corresponds to a weak water absorption. The most common rationale for including such a term as a divisor of the primary wavelength is to correct for fluctuations in the effective optical path length, generally caused by light scattering due to particulate matter in the sample. The second new term, at 1724 nm, corresponds to a weak protein absorption. This term, particularly in those samples with unusually high protein levels, may serve to correct for the contribution of protein absorptions to the intensity at 2152 nm.

For analytes that do not yield prominent absorptions in the spectra of the target specimens, the simple single-term Beer’s law relationship fails completely. One solution in this case is again to assume a solution of the type represented by Equation (3), whereupon the task becomes to determine how many and which wavelengths/frequencies should be included in the analysis. One approach is to regress the set of spectral intensities, for each wavelength, against the analyte concentrations for the calibration specimens. The single wavelength that provides the best correlation with concentration is then taken as the “primary” wavelength, and further regressions are carried out holding the primary wavelength fixed to determine additional terms to complement the single-term model. The same process may be used to determine divisor terms (see the first term of Equation 4).

The stepwise regression approach to determining MLR terms is not guaranteed to find the optimal set of wavelengths, particularly for complex specimens where many terms may be required. The general problem is illustrated by the fact that in a set of calibration spectra, each comprising 2000 absorbance values, there are 2.5 \times 10^{26} possible eight-term wavelength combinations. Brute-force evaluation of all possible eight-term MLR models is clearly out of the question, and there is an
ongoing search for more efficient methods. Recent developments include genetic algorithms to identify the optimal spectral regions. For example, an algorithm originally developed to identify diagnostic patterns in magnetic resonance spectra has been modified recently to seek out optimal spectral subregions for MLR.

3.2 Principal Component Regression and Partial Least Squares

The feature common to both of these approaches is that each spectrum is reduced to a sum of pseudospectra, or “loading vectors”. Each spectrum is newly represented by a unique set of “scores” – the set of coefficients required to reconstruct the original spectrum from the set of loading vectors. Typically, each of the spectra can be reconstructed to within the noise limits by a combination of typically 5–15 loading vectors, as compared to the hundreds or thousands of intensity values in the original spectra. The scores then provide the basis for quantitation.

The essential relationship in both the PCR and PLS methods takes the form of Equation (5):

\[
A = TB + E_A
\]  

(5)

With \( m \) spectra in the calibration set, each having \( n \) absorbance values, \( A \) is the \( m \times n \) matrix of the calibration spectra. The spectra are reconstructed as a product of \( B \) (\( h \times n \)), the new basis set of loading vectors, and \( T \) (\( m \times h \)), the scores. To reiterate, the key to the process is that each spectrum is reduced from a vector of length \( n \) (a row in \( A \)) to a new vector of length \( h \) (the corresponding row in \( T \)), where \( h \) is typically between 5 and 15.

The column matrix of concentrations \( c \) is also related to the loading vectors \( T \), according to Equation (6):

\[
c = Tv + e_c
\]  

(6)

Here, \( v \) is the matrix of coefficients that relates the scores to the concentrations.

The reader is referred to several works in the literature for fuller explanations of PLS and PCR methods. For the sake of the present discussion, we note the following features common to the two methods:

- The main challenge in developing a method is to decide how many (and, in the case of PCR, which) loading vectors to include.
- The overall performance of either method may be improved by eliminating superfluous spectral regions from \( A \).
- The modeling of the spectra provides a means to detect outliers (those spectra with extraordinarily large spectral residuals \( E_A \)).

3.3 Spectral Preprocessing

It is almost always necessary, or at least desirable, to preprocess the absorption spectra in some fashion; the aim is to enhance the spectral features that carry information regarding the analyte of interest, and effectively to suppress or eliminate superfluous features. The simplest form of “preprocessing” is the selection of appropriate wavelengths in MLR model development; the analogy in PLS and PCR is the selection of a limited spectral region (or regions).

The most common procedures are mean centering, variance scaling, and derivation. Mean centering simply subtracts the average of the calibration spectra from each of the individual spectra. Variance scaling involves first evaluating the standard deviation among spectra for the intensity at each wavelength. All spectra are then divided by the pseudospectrum of standard deviations, and hence scaled so the variance is unity at all wavelengths. This operation effectively enhances the prominence of features due to species of relatively low concentration, while suppressing the intensities of strong (and variable) absorptions. The procedure is therefore most appropriate for the analysis of minor components. Derivation is commonly used to eliminate random fluctuations in the baseline (first derivative) and slope (second derivative) of the absorption spectra. Another benefit is the effective narrowing of spectral features, which may enhance specificity in the analytical method. Note that the features in the second-derivative spectrum are inverted relative to the absorption spectra. Although the second-derivative spectra plotted in Figure 5 have been inverted to yield peaks rather than valleys at positions corresponding to absorption peaks, this convention is not followed universally.

4 SERUM ANALYSIS

These analyses play a critical role in diagnosing and monitoring a wide variety of disorders (see Table 3), and a typical central hospital laboratory typically carries out many thousands of such tests every month. In order for a new testing procedure to be accepted clinically it must meet well-defined accuracy and precision standards. Although practical considerations such as the degree of automation also play a role in the acceptability of novel methods, these issues lie outside the scope of this article. In this section we present the current state of the art in the IR-based analysis of serum.

4.1 Infrared Spectroscopy of Serum

Among the most common clinical serum tests are those for the most abundant organic species. For at least

$^b$ Serum albumin levels generally parallel to total protein levels.

$^c$ Desirable range (5th percentile to 75th percentile) for 40-year-old individuals. For men, the upper limit is 141 mg dL$^{-1}$; for women, the upper limit is 117 mg dL$^{-1}$ per year after 40.

$^d$ Desirable range (reference interval is somewhat wider).

Six of these, the MIR spectra are distinctive enough and the concentrations are high enough that they may be determined from the MIR spectra of serum. These include glucose, total protein, albumin, triglycerides, urea, and cholesterol. The basis for detecting and discriminating among the six analytes is illustrated by the spectra of the pure compounds shown in Figure 6. The NIR spectra also permit quantitation of the same six species.

Four comprehensive feasibility studies have been published, all of which differ in significant ways. Two were based upon MIR spectroscopy, and two on NIR spectroscopy. One MIR investigation used ATR spectroscopy, and another used dried serum films; the two NIR studies differed in more subtle, yet substantial, details.

4.2 Serum Analysis using Near-infrared Spectroscopy

Two major systematic investigations have been carried out. The first of these, reported in a pair of publications by Hall and Pollard,$^{17,18}$ was based upon a rapid-scanning NIR spectrometer. The authors reported analytical methods for urea, triglycerides, total protein, and albumin.

Because the absorptions of protein overwhelm those of other dissolved species, it proved possible to use a simple MLR model to quantitate serum total protein. The absorption spectra of albumin further proved to be clearly distinguishable from those of the remaining proteins (primarily globulins; see Figure 7), so that a second two-term MLR model was sufficient to determine albumin levels. Based upon the second derivatives of the absorption spectra, the two models were as shown in
Figure 6 MIR absorption spectra for selected serum constituents. The spectra for urea, glucose, and albumin were acquired for aqueous solutions using an optical path length of 6 µm (the spectrum of water has been subtracted). Those for cholesterol and tripalmitin (tripalmitidoylglycerol) were measured for solutions in carbon tetrachloride using an optical path length of 0.5 mm.

Equations (7) and (8):

\[
C_{\text{albumin}} = 15 - 4419A(2178 \, \text{nm}) + 3655A(2206 \, \text{nm})
\]

(7)

\[
C_{\text{total protein}} = 65 - 7821A(2064 \, \text{nm}) - 2373A(1440 \, \text{nm})
\]

(8)

The protein levels predicted by the NIR model are compared to the reference analytical results in Figure 8.

The models for urea and triglyceride quantitation, also based upon the second-derivative spectra, required eight and eleven PLS factors, respectively. The spectral regions employed as the basis for these models differed slightly: optimal for urea quantitation (Figure 8) was a combination of the ranges 1324–1800 and 2304–2370 nm, whereas triglyceride levels were optimally predicted by combining the ranges 1635–1800

Figure 7 NIR reflectance spectra (second derivatives) for albumin, globulins, and urea. Total serum protein may be quantified by the intensity of the serum absorption at 2064 nm, corresponding to minima (absorption maxima) in the albumin and globulin second-derivative spectra. Pollard, ‘Near-infrared Spectroscopic Determination of Serum Total Proteins, Albumin, Globulins, and Urea’, Clinical Biochemistry, 483–490, Vol. 26, © 1993 by the Canadian Society of Clinical Chemists.)

Figure 8 NIR-predicted serum urea and serum protein levels compared to reference analytical results (see also “NIR A” in Table 4). The line of identity is included. (Adapted by permission of Elsevier Science from J.W. Hall, A. Pollard, ‘Near-infrared Spectroscopic Determination of Serum Total Proteins, Albumin, Globulins, and Urea’, Clinical Biochemistry, 483–490, Vol. 26, © 1993 by the Canadian Society of Clinical Chemists.)
and 2035–2375 nm. The 1850–2025 nm range, spanning a very intense water absorption, was explicitly excluded from both models. This provides an example of how PLS modeling benefits from the exclusion of spectral segments that carry no relevant analytical information. These NIR analytical methods for serum total protein, albumin, urea, and triglycerides are summarized as part of the synopsis of methods presented in Table 4.

A more recent NIR investigation was identical in spirit to the inaugural studies but incorporated one substantial change in the experimental protocol. Although the early work was carried out using an optical path length of 0.5 mm, the more recent work used a path length of 2.5 mm. It is quite counter-intuitive to expect improved accuracy at this relatively long path length, because the region richest in solute absorptions (2050–2450 nm) is bordered by two strong water absorptions (see Figure 2). The accessible range within this window is substantially reduced as the optical path length is increased, by virtue of the further encroachment of the shoulders of the two water absorptions. It emerged, however, that this effect was more than compensated for by the enhanced signal-to-noise for solute absorptions in the spectral window that remained accessible.

Figure 9 demonstrates the accuracy of the second NIR study in assays for triglycerides, urea, and cholesterol. Although the analytical methods for total protein and albumin also proved successful, the attempt to quantitate serum lactate proved to be fruitless. The poor results for lactate are largely due to the relatively low serum concentration. Another contributing factor may be that the NIR spectrum is not rich enough to differentiate lactate from other dissolved species (the only NIR bands arise from the methyl group). The analytical methods for the other six analytes are summarized in Table 4. As indicated in Table 4, all methods were based upon PLS models and all made use of the same 2062–2353 nm spectral region.

The NIR quantitation of glucose is of extraordinary interest. This interest stems from the early promise of NIR spectroscopy as a means of monitoring blood glucose levels noninvasively. Indeed, one of the primary aims of the in vitro study was to delineate better the ability of NIR spectroscopy to quantitate serum glucose under ideal experimental conditions. The success of this endeavor is summarized in Figure 10, which superimposes a Clarke error grid on the scatterplot comparing NIR to reference glucose levels. The error grid serves as a template indicating regions corresponding to acceptable

$^c$ Two wavelength terms were required for the albumin and total protein MLR calibration models.
analytical errors (A, B) and regions corresponding to errors that would lead to dangerous or fatal clinical decisions (C, D, E). As the authors point out, this analytical method is not accurate enough to meet clinical demands but it is accurate enough to suggest that further investigation is warranted.

4.3 Serum Analysis using Mid-infrared Spectroscopy

The two comprehensive feasibility studies have followed two different paths to avoid the problems associated with transmission spectroscopy of the native serum. One of these made use of ATR spectroscopy of the liquid, and the second was based upon transmittance spectroscopy of dried serum films.

4.3.1 Attenuated Total Reflectance Spectroscopy of Native Serum

In this work the investigators sought to quantify glucose, total protein, cholesterol, triglycerides, urea, and uric acid on the basis of the MIR ATR spectra collected using a CIRCLE ATR cell (Spectra-Tech Inc., Shelton, CT, USA). It had been concluded on the basis of

Figure 9 Comparison of NIR-predicted serum analyte levels to reference analytical results (see also “NIR B” in Table 4). Open circles correspond to the calibration (training) set, solid circles to the validation (test) set and the solid line is the line of identity. (Adapted from K.H. Hazen, M.A. Arnold, G.W. Small, ‘Measurement of Glucose and Other Analytes in Undiluted Human Serum with Near-infrared Transmission Spectroscopy’, Analytica Chimica Acta, 255–267, Vol. 371, © 1998, with permission from Elsevier Science.)
an earlier study\textsuperscript{(22)} that the most critical factor in this procedure is careful cleaning of the zinc selenide ATR optical element between spectral acquisitions. Therefore, the more recent investigation included a cleaning cycle using first a detergent solution, then distilled water, and finally ethanol. The element was then dried by pressurized nitrogen before admitting the next sample. Finally, the specimen was allowed 30 s to reach thermal equilibrium (the cell temperature was kept at 37 ± 0.02°C) before the spectrum was acquired.

The accuracy of this approach is illustrated by the scatterplots in Figure 11. All of the IR-predicted concentrations were based upon PLS models, summarized as part of Table 4. The MIR ATR approach is substantially more accurate than NIR for the quantitation of serum glucose. Why is this the case? The answer relates to the nature of the glucose structure. A rich set of strong absorptions appears in the MIR region of 950–1250 cm\textsuperscript{-1}, corresponding to skeletal C–O stretching vibrations, whereas the NIR spectrum shows only a single absorption in the CH combination region (see Table 1) centered at 2270 nm. The combination bands involving glucose OH groups are very diffuse and are overlapped with the water absorption at 1935 nm to such an extent that they are essentially valueless.

4.3.2 Transmittance Spectroscopy of Dried Serum Films

When a small volume of serum is spread evenly on an IR-transparent window and allowed to dry, the resulting film may be used as the basis to quantitate at least six analytes. A large study based upon this approach used 200 specimens as the basis to develop PLS calibration models for glucose, triglycerides, total protein, albumin, cholesterol, and urea, and an additional 100 specimens to test the accuracy of these models.\textsuperscript{(23)}

A representative spectrum is shown in Figure 4. This spectrum is for a film dried from a 50:50 mixture of serum and aqueous potassium thiocyanate solution (4 g L\textsuperscript{-1}); the prominent absorption at 2060 cm\textsuperscript{-1} originates with the SCN\textsuperscript{-} ion. All serum specimens were diluted in this fashion prior to measurement, with the objective of using the absorption intensity at 2060 cm\textsuperscript{-1} to normalize the spectra and hence compensate for possible imprecision in preparation of the films. The specimens were prepared for IR spectroscopy by spreading 7 μL of the diluted serum evenly on the surface of a 13-mm-diameter BaF\textsubscript{2} window. Duplicate samples were prepared in each case, and the corresponding spectra were averaged for PLS analysis.

The PLS trials were preceded by a normalization stage (all spectra were normalized to a common integrated intensity in the SCN\textsuperscript{-} absorption at 2060 cm\textsuperscript{-1}). The second derivatives of the normalized spectra then served as the basis for the analyses. Scatterplots comparing the reference analytical levels to the IR-predicted albumin, total protein, glucose, cholesterol, triglycerides, and urea are shown in Figure 12. The corresponding PLS models and their analytical accuracies are compiled in Table 4. Attempts to quantitate uric acid and creatinine proved unsuccessful due to their relatively low serum concentrations.

We use the example of glucose to illustrate the procedure that is used to gauge the appropriate number of PLS factors to include in the final model. Recalling that the pool of spectra is divided into a calibration set of 200 samples and a validation set of 100 samples, the aim was to arrive at a final model that optimally extracted the analytical information latent in the calibration spectra. To guard against the possibility of overfitting, the IR-predicted analytical levels were typically compared to reference values for models with 1–15 factors. The trends illustrated in Figure 13 are typical; the standard error of calibration (SEC) in the calibration set specimens decreases rapidly as the initial factors are added, and then tends to plateau as all of the analytically relevant factors were extracted. Additional factors provide rapidly
Figure 11 Serum ATR MIR-predicted glucose, total protein, cholesterol, urea, and triglycerides plotted against the gold standard clinical assays, with the line of identity included for reference (see also “ATR” in Table 4). (Adapted from Heise et al. by permission of the Society for Applied Spectroscopy.)

Diminishing returns, and generally model spectral features that are unique to the set of calibration spectra (i.e. noise). This may be inferred by examining the corresponding trend in the standard error of prediction (SEP) for the validation set. Although the SEC and SEP are essentially identical for all models up to and including 10 factors, this is no longer the case for models including 11 factors or more – although the errors continue to diminish for the calibration set, the opposite trend takes hold for the validation set. The appropriate number of PLS factors corresponds to the point at which the standard error in the validation set begins to increase; this model, corresponding to 10 PLS factors, is equally accurate for the samples in the calibration and validation sets.
Figure 12 Scatterplots comparing MIR-predicted serum analyte levels to reference analytical results (see also “Film MIR” in Table 4). The line of identity is also plotted. The spectra were acquired for dried serum films (see Shaw et al.23).

Finally, the example of serum glucose provides a good demonstration of a useful feature of PLS modeling. The first PLS weight vector is a least-squares estimate of the spectrum of the analyte of interest; it is a weighted sum of all the calibration spectra, with the weights being the reference concentrations.12 If this estimate shows similarity to the spectrum of the pure compound, it may be inferred that the PLS model is soundly based in that it is incorporating spectroscopic patterns that originate with that species. To illustrate this, we have evaluated a PLS model for glucose based upon the absorption spectra (not their derivatives) of the dried films. The first PLS weight vector is plotted in Figure 15 together with the absorption spectrum for an aqueous glucose solution. The striking similarities between these two traces provide a good illustration of how this PLS weight vector can be used to support the validity of the PLS model as a whole. At the same time, it should be emphasized that the first weight vector does not always show such a strong resemblance to the IR spectrum of the target analyte. Particularly

Figure 13 Trends in the SEC and SEP with increasing number of PLS factors for a glucose quantitation model. The 10-factor model was chosen as optimal, based upon these trends (see Shaw et al.23).

Figure 14 Comparison of the scatterplots comparing MIR-predicted serum glucose levels to reference analytical results for the training (calibration) and test (validation) sets. Results are based upon the spectra of dried serum films using the 10-factor PLS model (see Figure 13 and “Film MIR” in Table 4), and the line of identity is superimposed on each plot.
Figure 15 Comparison of the spectrum of an aqueous glucose solution to the first weighting vector for a serum glucose PLS calibration model. Comparisons of this type can provide confirmation, as in this case, that PLS modeling is soundly based upon genuine spectroscopic features of the analyte of interest rather than chance correlations.

for weakly absorbing species of low concentration, the first weight vector – even for a soundly based PLS model – may incorporate compensating features from other components of the mixture that are as large as or larger than features ascribed to the species of interest.

5 SERUM AND BLOOD GLUCOSE

The analysis for glucose is probably the most common blood/serum test. Much of the demand arises from the requirement for frequent self-testing in the diabetic population, and the majority of attempts to quantify glucose using IR spectroscopy have been motivated by the prospect of a noninvasive in vivo test. Because NIR radiation penetrates tissue to depths of millimeters or more, and because an absorption spectrum may be measured for living tissue by using fiber optics or other arrangements, hope has been held out for a NIR method to quantitate blood glucose in vivo.\(^{(24,25)}\) Although this subject matter is reviewed elsewhere in this encyclopedia, the various in vitro NIR laboratory studies provide some interesting insights regarding the prospects for in vivo measurement.

In principle, serum or blood glucose may be quantified either by using MIR spectroscopy or by exploiting any of three sets of NIR absorptions, namely those corresponding to vibrational combination bands (2000–2500 nm), the first overtone absorptions (1400–1800 nm), or the second overtone bands (950–1250 nm). All of these have been explored in attempting to quantitate serum glucose,\(^{(24)}\) but there are surprisingly few published studies attempting to quantitate glucose in whole blood. Three MIR ATR investigations\(^{(26–28)}\) yielded methods with standard errors of 0.8–1.1 mM, whereas the lone report addressing the use of NIR spectroscopy for the measurement of glucose in whole blood reported a SEP of 2.2 mM.\(^{(29)}\) The PLS models are summarized in Table 5.

How accurate must the glucose analysis be in order to be acceptable clinically? One set of guidelines for clinical testing that has been adopted widely is that of Barnett.\(^{(30)}\) Under those guidelines, a new analytical method for blood or serum glucose method should agree with established methods with a maximum standard deviation of 0.28 mM. A more detailed examination of the clinical consequences of inaccurate glucose testing in diabetics has provided the “Clarke grid”\(^{(20)}\) (see Figure 10). Although the scatterplot superimposed on this grid represents a serum NIR analytical method with a standard deviation (SEP) of 1.3 mM relative to reference analyses (substantially larger than the allowable error limit suggested by Barnett), the method clearly approaches the criteria for acceptability set out by Clarke et al. As mentioned earlier in this article, the regions labelled A and B in Figure 10 correspond to clinically acceptable errors. The most serious deficiency of the NIR method is in the analyses for specimens with lower glucose concentrations.

To summarize the present state of the art: the most accurate NIR analysis of serum glucose, carried out using the spectral window and transmission path length optimal for NIR detection, approaches the level of accuracy required for clinical use; and the NIR detection of glucose in blood is less accurate, mainly due to the confounding influence of light scattering by the blood cells.

6 FETAL LUNG MATURITY DETERMINED BY INFRARED SPECTROSCOPY

Among the most common concerns with problematic pregnancies is the possibility that the baby, if born

\(^{4}\) Artificial neural network model.
prematurely, will suffer from respiratory distress syndrome. Failing to produce pulmonary surfactant properly, these infants have traditionally been at high risk of severe respiratory problems or even death. It was recognized in the late 1970s that the fetal lung maturity could be estimated by analyzing for lung surfactants in the amniotic fluid. These tests have been used as the basis for the clinical decision as to whether and when to induce labor, balancing the risk to the mother in continuing the pregnancy with the benefit to the fetus of further lung development within the womb.

The test that has gained widest acceptance is the determination of the amniotic fluid lecithin/sphingomyelin ratio, using thin-layer chromatography (TLC). By its nature, this is a time-consuming and labor-intensive test, and an alternative based upon fluorescence depolarization has been proposed and widely adopted. This procedure measures the ratio of surfactant to protein in amniotic fluid.

Both the lipid and protein constituents provide clear absorptions in the MIR spectra (Figure 16), and both the lecithin/sphingomyelin ratio and the surfactant/protein ratio may be determined from the IR spectra of dry amniotic fluid films. For the lecithin/sphingomyelin ratio determination, the values predicted from the IR spectra (a 14-factor PLS model incorporating the spectral region 2800–3200 cm\(^{-1}\)) showed a very good correlation \((r = 0.90)\) with the TLC values. Similarly, when surfactant/protein ratios (determined using the Abbott TDx analyzer) were used to calibrate the PLS model, the resulting IR-based analytical method closely reproduced the reference TDx assays (Figure 17).

By their nature, both the TLC and TDx reference methods are inherently less precise than, for example, the common serum assays. For that reason, the scatterplots illustrated in Figure 17 inevitably reflect imprecision in the reference analyses. To confirm that the PLS model is based upon the spectral features of surfactant constituents, and is not built upon an accidental correlation with reference analyses, Figure 18 compares the first PLS weight vector to an experimental spectrum. The region plotted in Figure 18 corresponds to CH stretching vibrations of the amniotic fluid constituents, and therefore includes the characteristic vibrations of the long lipid methylene chains as well as absorptions from the proteins. The experimental trace is a difference spectrum, obtained by subtracting the average of all IR spectra corresponding to surfactant/protein ratios less than 55 mg g\(^{-1}\) protein from the average of those with surfactant/protein ratios above that value. The similarity between these two traces confirms that the PLS model is founded upon genuine spectral features originating with the lipid and protein constituents of amniotic fluid.

7 OTHER FLUIDS

7.1 Urine Analysis

Two of the most common analytical tests are for urine creatinine and protein, both of which are key indicators
Figure 18 Validation of a PLS model to quantitate the amniotic fluid surfactant/protein ratio from MIR spectra of dried amniotic fluid films. The lower trace is the first PLS weight vector for a MIR quantitation model calibrated with reference to laboratory TDx measurements of the surfactant/protein ratio. The upper trace is a difference spectrum, obtained by subtracting the average of all IR spectra corresponding to surfactant/protein ratios of less than 55 mg g\(^{-1}\) from the average of those with surfactant/protein ratios above that value. The 2800–3000 cm\(^{-1}\) region proved nearly optimal for PLS calibration, with only marginal improvements gained by the addition of segments in the 900–1800 cm\(^{-1}\) region (see Figure 16).

\(^a\) From Wallach\(^{15}\) and Tietz.\(^{16}\) Diagnostic information is generally inferred from totals passed in urine over a 24-h period. Concentrations for the NIR study reported in Shaw et al.\(^{6}\) were grouped in the ranges 100–400 mmol L\(^{-1}\) (urea), 2.5–12.5 mmol L\(^{-1}\) (creatinine) and 0–3 g L\(^{-1}\) (protein).

7.2 Saliva

Because it is so readily available, saliva has often been considered as a potential source of diagnostic information.\(^{33}\) The MIR spectrum of the dried film (Figure 19) reveals not only the protein constituents but also thiocyanate (SCN\(^{-}\)). Although it is somewhat surprising to the layman to learn that this ion is present in appreciable amounts in human saliva, it plays a functional role; enzymatic conversion yields salivary hypothiocyanate (OSCN\(^{-}\)), which is a highly effective antibacterial agent.

The SCN\(^{-}\) ion shows an absorption in a spectral region that is typically devoid of any other bands. As a result, it proved possible to quantitate this ion in saliva through a simple Beer’s law relationship according to SEP of 0.79 mmol L\(^{-1}\). The best that could be achieved for protein was an 8-factor PLS model with a SEP of 0.23 g L\(^{-1}\). This model is clearly insufficient to provide the information that is sought most often clinically, because a protein level above ~0.1 g L\(^{-1}\) is considered to be a warning sign of possible kidney malfunction. In an effort to improve the accuracy of the IR-based method for samples with low protein concentrations, a second PLS model was derived using only those specimens with reference protein concentrations of less than 1 g L\(^{-1}\). Although the result was an improved accuracy in quantitating protein in the range 0–1 g L\(^{-1}\), the SEP of 0.12 g L\(^{-1}\) remained unacceptably high. With a detection limit of 0.36 g L\(^{-1}\) (taken as three times the standard error), many urine specimens have protein levels below the threshold that is detectable by NIR spectroscopy.

![Graph showing MIR spectrum of saliva](image)
Equation (9):

\[ C_{SCN} = -0.001 + 0.65A(2058 \text{ cm}^{-1}) \] (9)

where \( A(2058 \text{ cm}^{-1}) \) denotes the integrated intensity for absorption at 2058 cm\(^{-1}\) for a 5-\(\mu\)L saliva aliquot dried to a spot of diameter 4 mm. The same study indicated further that saliva thiocyanate concentration levels may follow a circadian rhythm, with maximum levels early in the day.

8 DISEASE DIAGNOSIS BASED ON INFRARED SPECTRAL PATTERN RECOGNITION

Although the analysis of biological fluids has a long tradition in providing information to suggest or corroborate diagnosis, a complementary technique is emerging for the interpretation of the IR spectra. Rather than deriving analyte levels explicitly from them, the spectra may be viewed as fingerprints that correlate directly with the presence or absence of disease. Because the spectra are complex, patterns characteristic of specific diseases are rarely (if ever) discernable from visual examination of the spectra. However, multivariate analytical methods may identify subtle patterns distinguishing the spectra corresponding to “normal” specimens from those corresponding to diseased patients.

The general procedure for developing this diagnostic test has much in common with the techniques employed to develop IR-based analytical methods. The first step is to acquire appropriate specimens from two sets of donors. One set of normal or control samples is required, whereas the second set corresponds to patients who have been diagnosed by traditional methods as having the disease of interest. The corresponding IR spectra are collected and subjected to two interlinked procedures: feature extraction and classification. The feature extraction procedure identifies characteristics that distinguish the normal spectra from diseased, whereas the aim of the classification stage is to separate optimally the two groups of spectra based upon those characteristics. Finally, the general applicability of the optimal classifier is tested by predicting the class assignments (normal or diseased) for a separate group of test spectra and comparing these a posteriori to the “gold standard” diagnoses.

8.1 Arthritis Diagnosis from Infrared Spectroscopy of Synovial Fluid

Synovial fluid is an ultrafiltrate of blood plasma that serves to transport nutrients to cartilage as well as to lubricate the joints. It is readily available for diagnostic testing (the fluid is commonly drained from joints that are inflamed, either as a result of disease or physical trauma), however there is no synovial fluid analytical test or combination of tests to reliably diagnose arthritis or to distinguish arthritic conditions from one another.

Two studies have suggested that the IR spectra of synovial fluid specimens provide the basis to diagnose arthritis and to differentiate among its variants. A NIR study demonstrated that osteoarthritis, rheumatoid arthritis, and spondyloarthropathy could be distinguished on the basis of the synovial fluid absorption patterns in the range 2000–2400 nm. In that case, the pool of synovial fluid spectra was subject to principal component analysis, and eight principal component scores for each spectrum were employed as the basis for linear discriminant analysis. On that basis, the optimal LDA classifier matched 105 of the 109 spectra to the correct clinical designation (see Table 7).

An investigation based upon the MIR spectra of dried synovial fluid films showed similar success in distinguishing spondyloarthropathy, rheumatoid arthritis, and osteoarthritis from one another and from control specimens (generally synovial fluid aspirates from individuals with injuries rather than diseased joints). This study is of interest in that it made use of a genetic region selection algorithm to identify a set of 15 discrete spectral sub-regions differentiating the 4 classes of spectra. With each spectrum represented by a set of 15 regional intensities, LDA provided the basis for successful classification.

Although applications of this type are not analytical in the traditional sense, they may provide analytical information indirectly. The successful classification of IR spectra according to disease type implies that the composition of the specimen is altered in a characteristic fashion with the onset of disease – in this case the synovial fluid make-up reflects the presence and type of arthritis. This is an intriguing finding, particularly as it is very unlikely that the IR spectra are detecting any particular constituent that cannot be (and has not been) assayed.

a The IR-based diagnoses are from principal component analysis and LDA of synovial fluid NIR spectra (see text): SA = spondyloarthropathy; RA = rheumatoid arthritis; OA = osteoarthritis. The table indicates, for example, that of the 29 spectra corresponding to patients with osteoarthritis, 27 were classified correctly but two were misclassified as rheumatoid arthritis. (see Shaw et al.)
previously. The strength of this approach therefore lies not in the ability of IR spectroscopy to identify novel disease markers, but rather in the ability of multivariate pattern recognition and classification methods to perceive characteristic changes in the balance among the IR-detectable components.

8.2 Disease Pattern Recognition in Mid-infrared Spectra of Serum

The premise underlying this research is that the combination of serum MIR spectroscopy with pattern recognition methods can distinguish healthy subjects from those with specific disease types. One report has demonstrated success rates of better than 90% in distinguishing diabetics from healthy subjects, type I from type II diabetics, and patients with rheumatoid arthritis from healthy subjects. Again, this work is intriguing because it is very unlikely that the IR spectra reveal any fundamentally new serum constituents as “disease markers”. Although the successful classifications indicate that the presence of disease is linked to specific relationships among specific spectral features, the challenge remains to interpret the physiological significance of those features. As research progresses in this area, we may anticipate that these characteristic relationships among spectral features will be interpreted to reveal characteristic relationships among serum metabolite levels distinguishing healthy from diseased donors.

REFERENCES

Infrared (IR) spectra of intact microbial cells are highly specific fingerprint-like signatures which are used to differentiate, classify, and identify diverse microbial species and strains. Microbial IR spectra are also useful to (1) detect in situ intracellular compounds or structures such as inclusion bodies, storage materials, and endospores, (2) monitor and quantify metabolically released CO2 in response to various different substrates, and (3) characterize growth-dependent phenomena and cell–drug interactions. The characteristic information, useful for microbial characterizations, is generally distributed over the entire IR region of the electromagnetic spectrum, i.e. over the near-infrared (NIR), mid-infrared (MIR), and far-infrared (FIR). The spectral traits can be systematically extracted from the typically broad and complex spectral contours applying resolution enhancement techniques, difference spectroscopy, and pattern recognition methods such as factor-analysis and cluster-analysis, and artificial neural networks (ANNs). Additional applications arise by means of a light microscope coupled to the IR spectrometer. IR spectra of microcolonies containing less than 10^3 cells are obtained from colony replica by a stamping technique that transfers microcolonies growing on culture plates to a special IR-sample holder. Using a computer-controlled x,y-stage together with mapping and video techniques, the fundamental tasks of microbiological analysis, namely detection, enumeration, and differentiation of microorganisms, are perspective integrated in one single apparatus.

1 INTRODUCTION AND HISTORY

The 1980s and 1990s have witnessed the emergence of sensitive, rapid and increasingly precise physical techniques for microbiological analysis. These new techniques range from mass spectroscopy (MS), molecular spectroscopy (including fluorescence, Fourier transform infrared (FTIR) and Raman spectroscopy), the application of laser technologies, and flow cytometry, to different separation techniques like gas chromatography and high-performance liquid chromatography. This development is paralleled by the dynamic advance of molecular genetic techniques in microbiology, which presumably will develop into most sensitive and specific tools for microbial characterizations in the future.

In 1911 W.W. Coblentz was probably the first scientist to suggest that biological materials can profitably be analyzed by means of IR spectroscopy. The use of IR spectroscopy as a means of differentiating between and
identifying bacteria was extensively reported as early as in the 1950s and 1960s.\(^3\) A critical review on this subject published in 1959 summarized that, although bacteria definitely exhibit IR spectra that are unique for individual strains, the identification of bacteria via IR techniques cannot be regarded as a practical scheme because it is too time-consuming and impractical a procedure.\(^3\) Because of the limited specifications of IR spectrometers at that time (sensitivity, time, and reproducibility), reports on IR applications to microorganisms became less frequent in the 1960s and had virtually ceased by the mid-1970s. The development of modern interferometric IR spectroscopy, the availability of low-cost minicomputers and powerful new algorithms of multivariate statistical analysis (MSA) and pattern recognition methodologies such as factor analysis and ANNs have contributed to the revival of IR spectroscopy as a means of characterizing microbial samples.

1.1 Objectives

This article describes details of recent technological developments, data elaboration methodologies, and representative examples of applications in this field. Only results that are concerned with samples of intact cells will be presented. No attempt will be made to comment on the use of IR spectroscopy for the analysis of isolated cell fragments, compounds, macromolecules, or cell metabolites.

1.2 Advantages and Disadvantages of the Method

Among the most important aspects of IR spectroscopy for investigating intact cells of microorganisms the following are noteworthy:

- **Advantages:**
  1. The method is uniformly applicable to virtually all microorganisms which can be grown in culture. Biomass requirements can be scaled down to single colonies taken directly from the culture plates. With the use of IR microscopes even microcolonies as small as 20 µm in diameter corresponding to a few hundred cells can be analyzed. Results are available within minutes after obtaining adequate samples of the pure culture.
  2. Detection, enumeration, classification, and identification can be integrated in one single instrument when using the IR microscope. Results are available within one working day in a clinical setting, including isolation, cultivation and identification.
  3. IR spectroscopy can classify microorganisms at very different levels of taxonomic discrimination without any preselection of strains by other taxonomic criteria. In contrast to most other techniques, IR spectroscopy is useful at the strain, species and genus level. The specificity of the method is generally extremely high allowing differentiations at the strain and/or serogroup/serotype level.
  4. These advantages make the method applicable to (i) very rapid identification of life-threatening pathogens; (ii) epidemiological investigations, conductance of case studies, screening of pathogens, hygiene control, elucidation of infection chains, therapy control, and detection of recurrent infections; (iii) characterization and screening of microorganisms from the environment, biotechnological process control, microbiological quality control in the food and pharmaceutical industries, and maintenance of strain collections.
  5. In a number of cases, in situ detection of specific cell components is possible (e.g. storage materials, spore formation, encapsulation of microorganisms) and drug resistance and cell–drug interaction can be monitored and characterized.

- **Notable disadvantages:**
  1. Only microorganisms that can be grown in culture and are available as pure cultures can be analyzed. Mixed cultures can only be investigated with the help of the IR microscope provided single colony growth is obtained.
  2. Classification and identification are based on the analysis of spectral fingerprints. Specific information on one or only a few specific compounds present in the cells is generally not available.
  3. Since the technique provides a spectral fingerprint of all cell constituents, stable results can only be obtained provided the microbiological parameters (culture medium, cultivation time, and temperature) can be controlled rigidly. Spectral databases that are used in different laboratories require the use of appropriate culture media available on the market.
  4. Acceptance of the IR technique by the microbiological community presupposes that spectral information can be transformed to classification schemes that are at least similar to those obtained by chemotaxonomic or by
molecular genetic techniques. This task can only be fulfilled by trained people in expert laboratories.

5. While the strength of the technique is its ability to differentiate microorganisms very rapidly below the species level, classifications at the genus level cannot be expected to be taxonomically relevant in all cases.

1.3 Infrared Spectroscopy

The IR region of the spectrum extends from the visible region until it overlaps the microwave, or very short radar, range at wavelengths of some millimeters (see Figure 1). The basic characteristic of this region is that the radiation originates from thermal emission from a hot source. Per convention throughout the IR region the “wavenumber”, that is the number of waves per centimeter, is used to characterize the radiation. The wavenumber unit is the reciprocal centimeter (cm$^{-1}$) and, hence, one is dealing with the convenient values of 1.000 cm$^{-1}$ to 10 cm$^{-1}$ throughout the IR region. Also per convention, the IR region of the electromagnetic spectrum is subdivided into the NIR, MIR, and FIR regions (Figure 1). An IR spectrum of a sample is obtained by scanning the intensity of IR radiation before and after passage of the IR beam through the sample. The IR spectrum is displayed by plotting the quantity $T = I_S/I_R$ as a function of wavenumbers, where $T$ is the transmittance, $I_S$ the intensity of the IR beam after and $I_R$ before passing through the sample. In most cases the absorbance $A$ is used ($A = -\log T$), since the absorbance at a given wavelength is directly proportional to the concentration of a sample according to Beer’s law. The IR spectra of most materials consist of a large number of absorption bands. These bands originate from the interaction (energy exchange) between discrete light quanta and mechanical motions (vibrational and rotational modes) of the molecules which are excited by the absorption of IR radiation. Since the constituents of a typical biological sample are present in a condensed phase (solids, liquids or solutions), only vibrational modes are observed. Consequently, IR spectra of biological specimens are only vibrational spectra.$^{15}$

1.4 Fourier Transform Infrared Spectroscopy

Technology: the Fourier Transform Infrared Spectrometer

With the advent of FTIR spectroscopy, major drawbacks of “classical” dispersive IR spectroscopy could be circumvented. Briefly, FTIR no longer measures one wavelength after the other and is not like dispersive spectrometers which are equipped with prism- and/or grating-monochromators where the light energy emanating from the IR source is strongly limited by several entrance and exit slits. FTIR, instead, applies interferometric modulation of radiation (see Figure 2). As in dispersive instruments, a hot white-light source (globar) is used in the MIR (block scheme, Figure 2a). A widespread type of interferometer used in FTIR is the so-called Michelson interferometer mounted with a KBr beam splitter coated with a germanium film to split the collimated IR beam into two parts (Figure 2b, upper panel). For rapid-scanning interferometers liquid nitrogen cooled mercury cadmium telluride (MCT) detectors are used. For slower scanning types of interferometer, pyroelectric detectors (e.g. a deuterated triglycine sulfate (DTGS) detector element) can be used. The moving mirror of the interferometer (Figure 2b, upper panel) yields a sinusoidal signal at the detector for each modulated frequency (see Figure 2b, central panel). For a white-light source all modulated signals superimpose to an interferogram as shown in Figure 2b, lower panel. This interferogram is amplified and digitized by the A/D converter (Figure 2a), computer stored, and finally transformed to a spectrum by fast Fourier transform (FT) techniques. Thus, the auxiliary computer in case of FTIR is a virtual necessity.$^{17}$ The interferometer can be thought of as a means of encoding the initial frequencies into a special form which the detector can observe. The most important feature of the interferogram is that every individual data point of this signal contains information over the entire IR region. In essence, the detector is always observing all frequencies at the same time. The Fourier transformation is simply a mathematical means of sorting out the individual frequencies for the final representation of an IR spectrum. This, along with some other features of the interferometer, leads to several distinct advantages.$^{7}$

1. The Jaquint Advantage. There are no longer slits in the interferometers that limit the amount of
Figure 2 FTIR spectrometer. (a) Block scheme of the basic components of an FTIR spectrometer. (b) Working principle of a Michelson interferometer consisting of a light source, beam splitter, fixed mirror, moving mirror, detector and a sample (upper panel). A single frequency light source (central panel, left) is modulated to a sinusoidal signal observed by the detector (central panel, right). A white-light source (e.g. emitted from a globar) is transformed to the interferogram (lower panel).

energy getting to the detector. The resolution of the FTIR spectrum is solely defined by the pathlength of the moving mirror away from the zeropoint (see Figure 2b, central panel). This advantage is particularly useful in cases where a small sample limits the optical throughput.

2. The Felgett Advantage. Because the detector is observing all frequencies simultaneously, the signal is said to be “multiplexed”. One complete scan of the moving mirror of the interferometer takes only a fraction of the time that a “dispersive scan” would need. Repetitive scans can be co-added and signal-averaged to reduce the random noise. Thus, very tiny signals may be extracted by decreasing the noise to a satisfactory level.

3. The Connes Advantage. The means by which the moving mirror position is monitored involves the use of an internal HeNe reference laser. This laser is also used as an internal wavelength calibration standard. Therefore, the wavelength accuracy of most of the FTIR spectrometers is specified to lie within 0.01 cm⁻¹, which is particularly useful when absorbance subtraction and resolution enhancement techniques are used and when stored spectra, for
4. The Stray Light Advantage. Because the interferometer modulates each IR frequency differently, there is no equivalence to stray light in FTIR. This means that the absorbance values remain very linear even beyond three absorbance units.

5. The Data Handling Advantage. Since FTIR is based on highly efficient minicomputers controlling the interferometer, collecting the digitized interferograms, and calculating the IR spectra, spectral data can now be easily stored on electronic devices and can be manipulated (resolution-enhanced, baseline-corrected, etc.).

2 CHEMICAL STRUCTURES AND COMPOSITION OF MICROBIAL CELLS

Understanding of IR spectra of microbial cells requires a general perception of its composition, major cell types, and chemical structures present, and knowledge of the differentiation of cells and tissues. At the simplest level all biological systems are composed of water, lipids, proteins, and carbohydrates. The gross composition of bacterial (prokaryotic), yeast, and mammalian (eukaryotic) cells is given in Table 1.

2.1 Bacterial Cells

In contrast to animal, plant, and yeast or fungal cells (so-called eukaryotic organisms) bacteria (also called prokaryotes) exist in only a limited number of morphological forms (e.g., rods, cocci, chains and spirals). Their chemical composition and structures, however, vary considerably. The cytoplasmic structures of bacteria are less organized (compartmentalized) and are simpler than those of yeasts and fungi, but have complex and diverse molecular and supramolecular structures outside the plasmic membrane. These include the cell wall, outer membrane, capsules and sometimes specific layers, e.g., the S-layers. Some bacteria are capable of sporulation or storage material production. Many structural differences providing the possibility of differentiation between bacteria by IR spectroscopy reside in the cell envelope, which is generally defined as the cytoplasmic membrane plus the cell wall.

Most cell envelopes fall in two categories: the so-called Gram-positive bacteria consisting only of the cytoplasm, the cytoplasmic membrane, and the cell wall; and the more complex Gram-negative which contain the so-called outer membrane in addition to the cell envelope. Some bacterial species, the mycoplasms, lack any cell wall at all, but express a rather rigid plasma membrane.

The bacterial cell wall is a rigid high-molecular network made up primarily of the peptidoglycan, which has a shape-giving function and protects the cells from osmotic disruption. Its primary structure consists basically of disaccharide–pentapeptide subunits with unusual features such as the occurrence of alternating D- and L-amino acids and a γ-bonded D-glutamic acid residue. Its structural variants are found to be different for various groups of bacteria. Additionally, a lipoprotein has been found to be covalently bound to the peptidoglycan of Gram-negative organisms. Many Gram-positive bacteria have an additional polymer, covalently bound to the peptidoglycan, the teichoic and teichuronic acids. The teichoic acids are ribitol or glycerol-containing macromolecules, built up by a phosphate-carrying backbone with side chains of variable composition. Teichuronic acids or neutral polysaccharides are also sometimes found in the Gram-positive cell wall. Gram-negative bacteria exhibit an additional membrane, the so-called outer membrane.

The outer membrane is an asymmetric membrane, the inner leaflet of which contains only phospholipids with nearly the same composition as found in the cytoplasmic membrane, while the outer leaflet contains exclusively one particular type of amphiphilic molecule, the lipopolysaccharides (LPS) and the various pore-forming proteins, the porins. The structure of LPS contains three basic regions: the so-called O-specific side chain (a hetero-oligosaccharide, responsible for O-antigenicity), the inner and outer core regions and a lipid anchor called lipid A. This outer membrane is the major permeability barrier that protects these cells against bile salts, degradation by digesting enzymes and

Data comparison, have to be transferred to different loci.
which prevents the cells from hydrophobic drugs and antibiotics diffusing through this particular layer. The mycobacteria, nocardia, corynebacteria, and some related groups have very unusual cell envelopes which form thick wax-like layers around the outside of the cell wall. Major compounds present in this impermeable and rigid layer are complex, long-chain fatty acids, the mycolic acids.\(^9\)

Some bacteria form capsules (sometimes referred to also as "slime layers") surrounding the cell envelope. These are not essential structures and are frequently built up of negatively charged polysaccharide compounds. Some bacilli exhibit capsules composed of negatively charged homo-oligopeptides such as poly-D-glutamic acids.

Many bacilli and clostridia may form endospores which are modified cell structures that can survive under unfavorable environmental conditions. These endospores have two membrane-like layers. Between these two layers, a spore-specific peptidoglycan (the so-called cortex) is found which differs in primary and three-dimensional structure from the peptidoglycan of vegetative cells in that the muramic acid of peptidoglycan is modified to a lactam derivative and is less cross-linked. A keratin coat is located on the cell exterior and it has been established that large quantities of Ca\(^{2+}\)-dipicolinate are related to heat resistance of endospores.\(^8\)

2.2 Yeast Cells

The proteins, lipids and polysaccharides that make up the membrane, cell wall, and capsules of capsulated yeasts have a significant impact on the systematics and phylogeny of yeasts. Only a small number of species of yeasts has been investigated in depth and even fewer studies have focused on structural details of these constituents.

The storage compounds in yeasts have been reviewed.\(^10\) The principal, readily mobilizable reserve polysaccharide in yeasts is glycogen (see also Figure 3). Glycogen occurs in yeast cells both in the cytoplasm and nucleoplasm either in soluble form or as aggregates of spherical particles having a diameter of 40–50 nm. The glycogen content of yeast cells is highly dependent on the physiological state and may reach up to 20% of the dry weight of the cells. Glycogen may have a molecular weight up to 10\(^7\); it contains three types of \(\alpha-(1 \rightarrow 4)\) linked chains of glycosyl units: short A-chains (side chains) attached to B-chains (main chains) by \(\alpha-(1 \rightarrow 6)\) glycosidic linkages. The main chains (carrying one or more side chains) are attached by \(\alpha-(1 \rightarrow 6)\)-glycosidic links.

The cell walls of yeasts are composed of complex polysaccharides and glycoproteins. The principal low-molecular building blocks of these polysaccharides are glucose and mannose followed by galactose, xylose, \(N\)-acetyl-D-glucosamine, and uronic acids. While the qualitative composition of these compounds is a taxonomic marker, the quantitative composition varies with cultivation conditions. Major structures of yeast cell walls are \(\beta\)-glucans in which the glycosyl units are mutually linked by \(\beta-(1 \rightarrow 3)\), \(\beta-(1 \rightarrow 6)\), and possibly \(\beta-(1 \rightarrow 2)\) glycosidic bonds. These structures are found with different molecular weights and branching and may form microfibrillar structures of crystalline nature.\(^11\) Chitin, a linear \(\beta-(1 \rightarrow 4)\) polymer of \(N\)-acetylgalactosamine is a typical constituent of primary septa and budding yeast.

![Figure 3 MIR-spectra of the main biological building blocks. DMPC; dimyristoylphosphatidylcholin; ct-DNA; calf thymus deoxyribonucleic acid; Hb; human hemoglobin; Gl; the carbohydrate glycogen. Spectra have been measured in H\(_2\)O and corrected for H\(_2\)O/buffer technique: absorbance/transmission (A/T); nominal physical resolution: 4 cm\(^{-1}\); apodization function: Blackman-Harris 3-term; number of scans: 128; detector: DTGS; spectrometer: IFS 66 (Bruker Optics, Germany).](image-url)
Chitosan, a β-(1 → 4)-linked polymer of D-glucosamine, may be considered to be a minor yeast polysaccharide but in dimorphic fungi belonging to the group of Zygomycetes it may represent one of the principal wall components. Mannans exist in yeasts as covalent complexes with proteins. The yeast mannoproteins are large molecules (molecular weight up to 500,000) consisting of a covalently linked carbohydrate and protein. The polysaccharide portion contains up to 150 mannosyl units, being connected via N-glycosidically linked polymannose units. A second group of carbohydrate of yeast mannans are short manno-oligosaccharides, O-glycosidically linked to serine and/or threonine residues of the polypeptide (protein). (11)

In some yeasts, particularly of the genus Cryptococcus, the polymers containing D-glucoronic acid residues are important constituents of extracellular capsules. For example, the capsule of Cryptococcus laurentii is made up of a α-(1 → 3)-linked mannose backbone with xylosyl and glucuronosyl residues as side groups. (12)

Yeast membranes contain a number of lipids and pigments that are not present in prokaryotic cells (bacteria). (8,13) These are sterols, sphingolipids, ergosterins, melanins, and some glycolipids. Culture conditions have a marked influence on the total lipid content and lipid composition of yeasts. Factors controlling lipid content and composition are pH of the medium, temperature, and time of growth, and the ratio of N- and C-sources. Sterols occur both in free form and as esters with long-chain fatty acids. Both forms are interconvertible. Free sterols are associated with membrane functions; sterol esters may fulfill a storage or “pool” function. Common sterol molecules of yeasts are ergosterol, lanosterol, episterol, zymosterol, and fecosterol. Major structures of sphingolipids found in yeasts are the sphingosines, cerebrins (ceramides), sphingomyelins, and cerebrosides. A typical membrane lipid in yeast is ergosterin. Its structure is similar to cholesterin and it belongs to the group of sterines. Further compounds frequently found in the membranes of yeasts are melanins which are black pigments built up from tyrosine derivatives. (8)

### 3 MAIN BIOLOGICAL BUILDING BLOCKS AND ASSIGNMENT OF INFRARED BANDS

IR absorption bands observed in the MIR region between approximately 800 and 4000 cm⁻¹ mainly arise from the fundamental vibrational modes and in the group frequency notion, can often be assigned to particular functional groups. At wavenumbers lower than 1400 cm⁻¹, IR bands tend no longer to arise from localized vibrational modes but rather from skeletal and strongly coupled modes, which are difficult to describe. For practical purposes, rough band assignments can be obtained from group frequency charts published in several bibliographies that may be helpful to obtain correlations between partial structures and band frequencies. Several spectra descriptions and excellent structure–spectra correlations for the most important biological macromolecules can be obtained from the literature. (14,15) Efforts to interpret the IR spectra of biological molecules are mainly based on the analysis of known structures, normal coordinate analysis and isotope exchange experiments. Nucleic acids, proteins, lipids, and carbohydrates are constantly present in different amounts and in a wide diversity in microbial cells. Figure 3 gives the MIR-spectra of a typical phospholipid, DNA, protein, and carbohydrate structure. Some of the IR bands are numbered and tentative assignments can be taken from Table 2.

Figure 4 shows IR spectra of fully hydrated samples of intact cells of Escherichia coli that span the entire MIR and NIR range from 1000 to 10,000 wavenumbers. The MIR spectrum of Figure 4(a) was obtained on a hydrated film sample with a thickness of about 8 µm. Figure 4(b) shows the NIR spectrum recorded on a sample with a film thickness of about 250 µm. In both cases CaF₂ was used as the optical cuvette material. The insets of Figure 4(a) and (b) give the second derivatives as calculated from the original absorbance spectra. Both the MIR and the NIR regions provide a large number of spectral traits that may potentially be useful to characterize complex biological materials such as microorganisms. Some rough assignments in respect to OH, NH and CH functional groups are given at the top of Figure 4.

Figure 5 (curve a) shows a MIR spectrum of a typical microbial sample dehydrated to a thin film layer on a ZnSe optical plate. While exact assignment to specific structures is still too complex a task, many spectral features of intact cells can be visualized by applying resolution enhancement techniques. In general 50–70 spectral features are resolved by derivative or Fourier self-deconvolution techniques (see Figure 5, curve b), and are the basis of assignments to functional groups, known chemical compounds, partial structures or different conformational states of particular molecules present. These spectral features constitute a spectral fingerprint useful for differentiating between different types or states of cells.

IR spectra of microbial specimens provide not only a number of absorption bands that describe molecular composition of the cells. Many of these bands are also sensitive to structural changes, various intra- and intermolecular interactions including H-bonding pattern, membrane constitution, lipid–protein interaction, and conformational states like different secondary structures of proteins. The physical state of the sample such as hydration or aggregation state, interaction with ions
Table 2: Tentative assignment of some bands frequently found in microbial IR spectra (peak frequencies have been obtained from the second derivative spectra)\(^a\)

asym = asymmetric; sym = symmetric; str = stretching; def = deformation.

and so on has a strong influence on results. These facts necessitate the rigorous standardization of sampling, preparation, and data acquisition procedures.\(^{6,16–18}\)

Tentative band assignments based on the systematic comparison of resolution-enhanced microbial IR spectra with those of the known building blocks constantly present in intact cells can be derived from Table 2 (see also spectra of Figure 3 for comparison):

Figure 4: IR absorbance spectra of a fully hydrated sample of Escherichia coli (strain RKI/A 139) in the spectral range between 1000 and 10000 cm\(^{-1}\) (a) MIR; (b) NIR. The insets show the second derivatives as calculated from the original absorbance spectra. Physical resolution applied was 6 cm\(^{-1}\) for the MIR and 16 cm\(^{-1}\) for the NIR measurements, respectively. Technique: A/T; cuvettes: CaF\(_2\) windows with 8 \(\mu\)m (MIR) and 250 \(\mu\)m (NIR), respectively; number of scans: 64 (MIR, DTGS-detector), 512 (NIR, InSb-detector); apodization function: Blackman-Harris, 3-term; spectrometer: IFS 66 (Bruker Optics, Germany).

1. The region between 4000 and 3100 cm\(^{-1}\) is dominated by rather broad spectral features resulting from –OH (~3400 cm\(^{-1}\)) and N–H stretching modes (amide A ~ 3300 cm\(^{-1}\) and amide B ~ 3030 cm\(^{-1}\)).
2. The region between 3100 and 2800 cm\(^{-1}\) exhibits the C–H stretching vibrations of \(-\text{CH}_3\) and \(>\text{CH}_2\) functional groups and, hence, is generally dominated by the spectral characteristics of fatty acid chains of the various membrane amphiphiles (e.g. phospholipids) and by some amino acid side-chain vibrations. Complementary information can be deduced from the region between 1470 and 1350 cm\(^{-1}\), where the various deformation modes of these functional groups are found. In rare cases, a weak band near 3015 cm\(^{-1}\) is also observed, resulting from \(=\text{C}–\text{H}\) double bond stretching modes of unsaturated fatty acid chains.

3. The region between 1800 and 1500 cm\(^{-1}\) is dominated by the conformation-sensitive amide I and amide II bands, which are the most intensive bands in the spectra of nearly all bacterial samples so far tested. Since IR spectroscopy is an averaging technique, the amide I and amide II bands cannot provide structure information on a single protein; they rather indicate the predominance of \(\alpha\)- or \(\beta\)-structures present. Useful information can also be obtained from bands near 1740 cm\(^{-1}\), resulting from \(\delta\)–CO stretching vibrations of the ester functional groups in lipids. Absorptions of nucleic acids can also be expected in this spectral domain due to \(>\text{C}=\text{O}, >\text{C}=\text{N}, >\text{C}–\text{C}<\) stretching of the DNA or RNA heterocyclic base structures.\(^{14,15}\) A band near 1715 cm\(^{-1}\), which is assigned to a \(>\text{C}=\text{O}\) stretching vibration, is routinely observed in the spectra of hydrated microbial cells and tissue material, and is known as a sensitive probe of base pairing in nucleic acids. Weak features of nucleic acids between 1600 and 1700 cm\(^{-1}\) are often overlapped by the much stronger protein amide I bands, since the relative amount of DNA or RNA per cell mass generally does not exceed 10% w/w. Weak bands, which can be assigned to amino acid side-chain vibrations, occur near 1498 cm\(^{-1}\) (phenylalanine), 1516 cm\(^{-1}\) (tyrosine) and between 1585 and 1570 cm\(^{-1}\) (aspartate and glutamate carboxylate stretching).

4. Complex absorption profiles are observed between 1300 and 1500 cm\(^{-1}\) arising predominantly from \(>\text{CH}_2\) and \(>\text{CH}_3\) bending modes of lipids and proteins. A characteristic, but weak, feature is often observed around 1400 cm\(^{-1}\), which may be attributed to the symmetric stretching vibrations of \(-\text{COO}\)^\(^{-}\) functional groups of amino acid side chains or free fatty acids.

5. Around 1230 cm\(^{-1}\) superimposed bands typical of different \(>\text{P}=\text{O}\) double bond asymmetric stretching vibrations of phosphodiester, free phosphate and monoester phosphate functional groups are observed. In most cases, three to four different weakly pronounced features can be discriminated by resolution enhancement, with the band near 1220 cm\(^{-1}\) being
most probably due to the phosphodiester functional groups of DNA/RNA polysaccharide backbone structures. The other >P=O double-bond stretching frequencies are due to head group vibrations of phospholipids or, for example, the phosphorus-containing carbohydrates such as “teichoic acids” and “lipoteichoic acids” (charged polymers, which may be present in substantial amounts in Gram-positive bacteria).

6. The spectral region between 1200 and 900 cm⁻¹ is generally dominated by the symmetric stretching vibration of PO₂⁻ groups in nucleic acids and a complex sequence of peaks mainly due to C–O–C and C–O–P stretching vibrations of various oligo- and polysaccharides.

7. The region between 900 and 600 cm⁻¹ exhibits a variety of weak, but extremely characteristic, features superimposed on an underlying broad spectral contour. This region may contain weakly expressed bands arising from aromatic ring vibrations of phenylalanine, tyrosine, tryptophan and the various nucleotides. With the exception of only a few peaks (e.g. a band near 720 cm⁻¹, resulting from the >CH₂ rocking modes of the fatty acid chains), valid assignments can hardly be achieved. Therefore, we refer to this spectral domain as the “true fingerprint region”.

4 EXPERIMENTAL METHODOLOGIES

A major advantage of IR spectroscopy is that almost any kind of material can be measured and that it is not limited to the physical state of the sample (samples may be solutions, viscous liquids, suspensions, inhomogeneous solids or powders). Additionally, there are no principal restrictions to recording IR spectra of a given sample under very different physicochemical conditions with respect to temperature, pressure, state of dispersion, pH and so on. This is of advantage for biomedical analyses, since it is imperative to test biological specimens under conditions that leave the sample’s structures “as they are”, preferentially hydrated, unperturbed and nondisintegrated.

4.1 Infrared Measurement Techniques for Microbial Samples

In general, biological samples of microorganisms do not behave ideally. Different biological specimens should be compared under conditions where (1) IR absorbances of the samples to be compared are not too different, (2) IR bands are not too intensive in order to avoid detector nonlinearities, (3) Beer’s law is at least approximately obeyed, (4) signal-to-noise ratio is sufficiently high, and (5) varying baseline shifts caused by diffuse scattering at the sample surface and/or by inhomogeneity within the sample itself is minimized. These requirements are best fulfilled by using the traditional A/T, absorbance/reflectance (A/R), and the attenuated total reflection techniques.

4.1.1 Absorbance/Transmission Measurements

A/T spectra can be obtained from liquid solutions, dispersions or suspensions, from viscous or solid films cast on suitable IR transparent plates. Since water is the medium ubiquitously present in all biological samples, water-insoluble and IR transparent optical materials have to be used. These are CaF₂, BaF₂, ZnSe, ZnS, KRS-5, or germanium which differ in refractive index, spectral transparencies, and water solubility. Table 3 surveys relevant optical properties of these materials. Different cuvette systems have been described in the literature for A/T–IR measurements.

</table>
of microbial samples. Two versatile technical solutions for the consecutive measurement of microbial samples (dried film samples or aqueous solutions, suspensions or gel discs) are given in Figure 6.\(^{(6,19)}\)

### 4.1.2 Absorbance/Reflectance Measurements

A/R measurements (sometimes also called “external reflectance”) can be performed on the same samples used for A/T. The samples are placed on a light-reflecting instead of transmitting medium (e.g. silver, gold or polished stainless steel) which leads to a double-passage or, for special A/R devices, even a multipassage of IR radiation through the sample. At a grazing incidence of light, molecular monolayers, e.g. from lipids, may be measured as well.\(^{(5,7)}\)

### 4.1.3 Attenuated Total Reflectance Measurements

For an attenuated total reflectance (ATR) experiment, the sample is no longer placed in the path of the propagating IR beam as it is for A/T or A/R experiments, but is brought into contact with the surface of an internal reflection plate or prism, where it can interact with the IR radiation evanescing from the optically denser (ATR plate) to the rarer (sample) medium.\(^{(20)}\) The penetration depth of the electromagnetic wave into the rarer medium is defined by the wavelength dependent ratio \(n_2/n_1\) of the refractive indices of the denser \((n_2)\) and the rarer \((n_1)\) media and by the angle of incidence \(\alpha\) and is in the order of a few micrometers. For a defined ATR element \((n_1)\) and angle of incidence, the effective optical pathlength is constant or similar for different samples that have comparable refractive indices and provided the optical contact between the ATR
Figure 7 Schematic drawing of a multisample ATR cuvette: (1) ZnSe prism with five marked sample areas S; (2) demountable, hermetically sealed cartridge (two parts) carrying the ATR prism (1); (3) sliding carriage of the cartridge by which the ZnSe prism (sample areas S) may be moved through the IR beam for consecutive measurements; (4) cartridge drive; (5) housing with reflecting optics; (6) IR beam. (Adapted from Naumann et al. [6])

4.1.4 Diffuse Reflectance Measurements

Diffuse reflectance (DR) measurements of highly scattering samples like freeze-dried biological specimens, surface-rich materials like catalytic or chromatographic carriers, and finely ground or powdered materials can be performed using standard accessories supplied by most manufacturers of FTIR spectrometers. (7) A thin-layer chromatography accessory useful for FTIR measurements of dried microbial samples in DR has been described. (21)

4.2 Sampling of Microbial Cells and Data Acquisition

In order to obtain reproducible results, sampling of biological species, sample treatment procedures, IR measurement techniques, and IR acquisition parameters have to be controlled and standardized rigidly. There is no simple and uniform answer to all these requirements. For microbial analyses standardized experimental protocols including data acquisition and evaluation procedures have already been published. (6, 17–19) These standardization efforts have been stimulated by the necessity to exchange spectral data between different laboratories and to construct validated reference databases for routine identification of microorganisms isolated in different laboratories.

IR spectra may be obtained with sufficient reproducibility from microorganisms provided the microbiological parameters influencing cell growth (composition of growth media, incubation time, temperature of growth etc.) can be controlled and standardized. Compared with these requirements sample collection, sample preparation, and spectroscopic data acquisition parameters (spectral resolution, scanning time etc.) are of secondary importance. Microbial samples suitable for IR measurements can be obtained either from liquid cultures or directly from solid agar plates. These samples can be measured as hydrated pellets or dried films applying either the A/T, A/R or ATR techniques.

Using the A/T technique a typical simple protocol runs as follows. Subcultured microbial strains are cultivated on appropriate solid nutrient agar plates. Time and temperature of growth depends on the type of microorganism tested (e.g. 24 h at 37°C for many human pathogens). Small amounts of microorganisms are carefully removed from the agar plate with a standard calibrated (e.g. 1 mm in diameter) platinum loop and are suspended in 80 µL of distilled water. Subsequently, 30 µL of the suspensions are transferred to the water-insoluble IR transparent optical plate as small drops covering predefined sample areas of the ZnSe plate of the multicuvette system shown in Figure 6. The drop of microbial suspension is then dehydrated in a desiccator over a drying agent (P2O5 Sicapent from Merck or Silicagel) applying a moderate vacuum (∼25 Torr) to form transparent film discs suitable for A/T–IR measurements. The optical plate is then sealed in a gas-tight cuvette-cartridge to control humidity and to prevent the instrument from contamination and is transferred to the automatic cuvette holder of the instrument. The physical parameters have to be kept constant for all measurements to be compared. A suitable set of physical parameters is as follows: 6 cm⁻¹ nominal physical resolution, Blackman–Harris three-term apodization function, and a sufficient number of scans to reach a signal-to-noise ratio better than 3000:1. It is advisable to take the single beam reference spectrum through an empty place of the multisample cuvette system directly before the single beam sample spectrum is obtained. This eliminates virtually all contributions from impurities on the optical materials and minimizes problems arising from water vapor and CO2 bands caused by possible instabilities of the instrument and of dry air purging of the system. (6, 17–19)
4.3 Variability of the Microbial Specimen and the Problem of Reproducibility

The enormous diversity of microbial species and strains makes it an absolute necessity to perform measurements on statistically significant numbers of samples on hundreds if not thousands of different species and strains of microorganisms. The most important factors influencing data quality are repeatability and reproducibility of measurements. First, different levels of reproducibility that define and limit the discriminative power of the IR technique have to be considered. For quantification purposes it is useful to define different reproducibility levels (RLi) of repetitive IR measurements on microbiologically identical strains:6,17,18

- (RL1) that describes repeatability of independent IR measurements on samples prepared, e.g. from aliquots of one and the same aqueous suspension of microorganisms
- (RL2) that defines repeatability of independent IR measurements on samples prepared from aliquots of microbial suspensions with the microorganisms grown on the same agar medium produced from different batches over a sufficient period of time (e.g. one year).

To calculate quantitative numbers for these RL, an objective measure for description and comparison of independent IR measurements is necessary. One possibility is the crosswise calculation of correlation coefficients 2 (Pearson's product–moment correlation coefficient) between pairs of measured spectra according to Equation (1).

\[ r_{y1y2} = \frac{\sum_{i=1}^{n} y_{1i}y_{2i} - ny_{1}y_{2}}{\sqrt{\sum_{i=1}^{n} y_{1i}^2 - n\overline{y}_{1}^2} \sqrt{\sum_{i=1}^{n} y_{2i}^2 - n\overline{y}_{2}^2}} \]  

\[ (1) \]

\[ y_{1i} \text{ and } y_{2i} \text{ are the individual absorbance values of the two spectra to be compared; } n \text{ is the number of data points in the given frequency range; } \overline{y}_{1} \text{ and } \overline{y}_{2} \text{ are the arithmetic mean values of } y_{1} \text{ and } y_{2}. \]

From the correlation coefficient 2, a so-called differentiation index 2 may be defined according to Equation (2):

\[ D_{y1y2} = (1 - r_{y1y2})1000 \]  

\[ (2) \]

where 2 is the correlation coefficient. D may adopt values between zero and 2000, with zero for identical spectra (or spectral ranges), 1000 for completely noncorrelated and 2000 for completely negatively noncorrelated spectra.6,17,18

Mean D values between 0.4 and 0.8 for RL1 and between 7 and 10 with Poisson-like distributions of calculated individual D values for RL2 are obtained in practice when analyzing the first derivatives in the spectral range between 900 and 1200 cm\(^{-1}\) of dried microbial film samples with the cuvette system shown in Figure 6.6,17,18 RL1 is generally one order of magnitude lower than RL2. Hence the microbiological parameters (quality of growth medium, cultivation, and sampling of bacterial biomass, e.g. from the surface of solid agar plates) define the repeatability of IR measurements on microorganisms. The comparison of strains from different species or genera may yield D values higher than 300.6,17–19 Obviously IR spectroscopy provides considerable spectral variance that can be utilized to discriminate between different microorganisms.

5 DATA TREATMENT AND EVALUATION TECHNIQUES

Because thousands of measurements on hundreds of different species and strains of microorganisms have to be evaluated and compared for spectral similarity/dissimilarity, the use of multivariate data compression and pattern recognition techniques is a necessity. While univariate statistical analysis considers only a single property of a given object (e.g. a single intensity at a given wavenumber), multivariate statistics evaluate several properties of the objects at the same time. In this way the interrelationships between the properties of the objects can also be taken into account. The arsenal of multivariate statistical techniques provides ample methodologies for the pretreatment, evaluation, and representation of huge and complex data structures. Of the large number of pattern recognition techniques available, three are of particular interest when IR spectra of microorganisms have to be analyzed. These are factor analysis, hierarchical clustering, and ANNs.22–26

Factor analysis is primarily used to achieve data reduction. Hierarchical clustering, a so-called unsupervised classification method, attempts to find intrinsic group structures within the data set without the need of any class assignment nor partitioning of the data into a training and test data set. ANN analysis on the other hand is a supervised classifier by which the class assignment of each individual object is needed from the beginning. Partitioning of the whole data into a training and a test data set is needed to ensure reliability of results. Robustness of classification is further enhanced by cross-validation using the stringent “leave-one-out” method.
5.1 Factor Analysis

Briefly, the goal of factor analysis is to extract essential information from mixed and large data sets and to attain the classification of pattern. As in any MSA technique, the objects (here IR spectra) are first represented as points in hyperdimensional space with as many dimensions as there are properties (in our case digitized absorbance values at discrete wavenumber positions). The procedure of how data compression is achieved by factor analysis is shown schematically in Figure 8.

Beginning with a primary database, the spectral range of interest is selected, eventually filtered (e.g. by calculating the first or second derivative, or by applying a band pass filter or Fourier self-deconvolution); finally the spectra are normalized (e.g. by peak or vector normalization). The aim of factor analysis is now to calculate by a specific eigenvector/eigenvalue analysis a new variance-weighted coordinate system which is adapted to the characteristic structure of the data cloud. The orthogonal vectors of this new coordinate system, the so-called eigenvectors (in our case “factor spectra”), then represent characteristic structure information of the complex data cloud. In this way the objects (IR spectra) can be represented in the new, variance-weighted coordinate system as a function of specific properties of the whole data set rather than as a function of absorbances or frequencies. Typically, the first 2–24 eigenvectors of the new coordinate system represent, to a decreasing amount, the bulk of interspectra variance. The higher indexed eigenvectors (factor spectra) soon represent predominantly merely noise. Since the original IR spectra can be represented in this new coordinate system by only 2–12 numbers (factorial coordinates or factor loadings) compared to the 2000–4000 absorbance values of an MIR spectrum, a considerable data reduction is achieved, which allows the structures within the data cloud to be recognized. The mathematics of factor analysis are generally described in the matrix notation. This notation allows the use of general metrics (e.g. Euclidean metrics for principal component analysis (PCA) or chi-squared metrics for correspondence analysis). For more details, the reader is referred to the literature.

Figure 9 shows a so-called PCA map calculated from a data set of approximately 140 spectra collected from independent measurements on 13 different species and strains comprising Gram-positive and Gram-negative species.
Cluster analysis aims to classify objects, i.e. the description of the structure and property interrelationships intrinsic to a given set of objects each defined by a multiplicity of properties. The various classification algorithms use different distance measures to calculate similarity between the objects (e.g. correlation coefficients, Euclidean distances, Mahalanobis distances). Starting from the calculated distance matrix, an attempt is made to partition the objects into groups, classes or clusters, such that all objects belonging to the same cluster are as similar as possible and all objects belonging to different clusters are as different as possible, which means that intraclass variance should be as small as possible, while the interclass variance is a maximum. Often it is sufficient to find classifications that are only locally optimal. So far all hierarchical cluster analysis techniques are of approximative character. All cluster analysis techniques can be divided into hierarchical and nonhierarchical procedures. In most cases the hierarchical techniques are favored, since it is assumed that they describe best the inherent hierarchical structure of class-division within the given data set. The various different hierarchical cluster analysis techniques are generally distinguished between divisive and agglomerative methods. Divisive techniques are thought to be more potent, but much more computer intensive. Thus, the agglomerative techniques are used more frequently. All agglomerative clustering procedures work according to the same hierarchical ascendant principles: (1) in the beginning there are \( n \) objects that have to be classified, (2) then the two objects lying closest have to be found and are collected in one cluster, (3) the distances between this new cluster and all other objects are calculated, (4) in a next step, a search is made for the next nearest objects or clusters which are collected in one cluster. This procedure is repeated until all objects are collected in one single cluster. The history of hierarchical classification analysis is represented by a minimal spanning tree, also called a dendrogram, in which the merging process of classes can be followed visually. These classification schemes cannot provide an objective criterion of best partitioning. In one way or other, the number of classes has to be predetermined by the user, who needs at least some a priori knowledge about the inherent class structure of the data cloud. It is possible to provide the user with additional information that facilitates the interpretation (e.g. a curve showing the number of classes in a hierarchical cluster analysis calculation versus intraclass variance), but the final decision if the partition is useful or not is subjective. Hierarchical cluster analysis can be applied directly to IR spectra (the objects) represented in spectra space as points in hyperdimensional space with as many dimensions as there are encoded absorbance values, or to the IR spectra represented in a data compressed form in factor space with as many dimensions as there are factorial coordinates (factor loadings) selected for data representation (see Figures 10a and b). Adequate distance measures used

Figure 9 PCA map as calculated from a data set of 143 IR spectra obtained from Gram-positive and Gram-negative bacteria comprising repetitive measurements on 13 different species and strains. For projection of data, the factorial coordinates (factor loadings) \( F_1 \) and \( F_2 \) are used. As input data, the normalized first derivatives in the spectral ranges of \( 2800–3000 \text{cm}^{-1} \) and \( 1400–1500 \text{cm}^{-1} \) have been used. Derivation, normalization, and PCA (factor analysis) were performed using the software OPUS Vers. 3.0 (Bruker Optics, Germany running, under OS/2 Warp Vers. 3.0 (IBM, USA)).

Strains of microorganisms. The map has been constructed by two-dimensional projection of eigenvectors (factor spectra) 2 and 3 such that the intrinsic group or class structure of the whole data set can be inspected by eye. Each point in the map represents a spectrum, the factorial coordinates (factor loadings) 2 and 3 are used for data representation. PCA was applied using the normalized first derivatives in the spectral ranges between \( 2800–3000 \) and \( 1400–1500 \) wavenumbers as input data. Two diffuse clouds can be distinguished with the upper and lower clouds representing exclusively the Gram-negative and the Gram-positive bacteria, respectively. Since the spectral ranges used are known to represent the spectral characteristics of the \( C=H \) stretching and deformation vibrations of the \( CH_3, CH_2, \) and \( CH \) functional groups, respectively, this finding is caused because these Gram-positive and Gram-negative organisms differ in carrying (Gram-negative) or not carrying (Gram-positive) a membrane structure additional to the cytoplasmic membrane, the outer membrane, which, in turn, leads to specific differences in the spectral range where the various \( C=H \) stretching bands of the membrane’s lipids are expressed.\(^\text{6,17}\)
Figure 10 Minimal spanning trees, also called dendrograms, that graphically show hierarchical cluster analysis results on the same 143 spectra of Gram-positive and Gram-negative microorganisms shown in Figure 9. (a) Dendrogram obtained when the interspectral distance matrix is calculated in spectra space using $D$ value calculation of spectral distances as defined by Equation (2). (b) Dendrogram obtained when interspectral distances (Euclidean) are calculated in factor space after data compression using the first six factors. Cluster and factor analysis are based on the first derivatives in three spectral ranges (2800–3000, 1400–1500, and 900–1200 $\text{cm}^{-1}$) each separately vector-normalized. For cluster analysis the Ward’s algorithm was used. Factor analysis, hierarchical clustering, derivation, and normalization were performed using the software OPUS Vers. 3.0 (Bruker Optics, Germany) running under OS/2 Warp Vers. 3.0 (IBM, USA).
to calculate the spectral distances between the objects in spectra or factor space can be, for example, the Euclidean distance or the Pearson's product momentum correlation coefficient. The decision which is the best algorithm for cluster analysis and the optimal distance measure for calculating the distance matrix has to be found by trial and error. Satisfactory results on IR spectra of complex biological molecules can be expected from the Ward's and the so-called average linkage algorithms using the Pearson's product momentum correlation coefficient as a distance measure.\(^{(17,18)}\)

### 5.3 Artificial Neural Networks

In contrast to cluster analysis, ANN analysis is a supervised classification approach that needs a priori knowledge of the group or class structure of the data.\(^{(25,26)}\) ANNs are self-adaptive, parallel machine-learning systems made up of simple processing units, which have a natural propensity for storing experimental knowledge and making it available for practical use. ANNs are primarily used for pattern recognition purposes. They resemble the connectivity in brain in two respects. The first is that knowledge is acquired by the network from a learning process and in the second the interneuron connection strengths, known as synaptic weight, store the acquired knowledge. Several models of information processing of biological systems are used as an analogy. In nerve cells (neurons) the following abstract elements can be defined: (1) synapses which have chemical signal substances, (2) dendrites, where the incoming signals are received and processed, (3) the cell nucleus (kernel) which controls this process, and (4) axons, which propagate the impulse irritation forward. The incoming weights are calculated via different input layers of adjacent cell connections. After summation, an impulse is induced according to the strength of the weighted signals. The propagation function transports the impulse to a new cell, or directly to the output layer. The mathematical functions involved in this process are: (1) an activation function, (2) a description of the activation state of the neuron and (3) an output function. The activation function describes how a new activation state is developed from a preceding state of the neuron. The activation state defines the degree of activation and the propagation function has to weigh and combine all incoming signals. Therefore, a summation is often used as an algorithm. The value produced by the propagation function is used as input by the activation function. The activation function then produces the output. Binary, linear, sigmoid, and logarithmic functions are used as activation functions. The connecting network defines the manner in which the architecture of the network operates. For feed-forward ANNs, the information propagates from the input layer through the hidden layer(s) to the output layer. During training the reaction value is compared with the expected value at the output of the net. As long as deviations occur, the extent of the deviation is used as a measure of, how strong and where the weights are to be changed to minimize the output error. The second group of algorithms used are the feedback nets which can feed back the outgoing information from the neurons to a preceding layer. Examples are the so-called Hopfield, Elman, and Jordan nets. A supervised ANN requires a desired output for each input vector (spectrum) which is then compared to the actual output generated at a certain stage of analysis. A couple of learning strategies and learning rules are used to obtain incremental changes in the weights in order to optimize an error criterion. The learning strategy attempts to minimize a global error function for the given set of training data. The process of computing local errors for each processing element for optimization of the weights is continued interactively until the error is minimized to an acceptable value. The advantage of ANNs is that they can be used as self-learning parallel working machines. ANNs can be trained using a maximum of repetitive measurements on each of the objects to be compared. The redundant information is then ignored, only the significant information is stored. This saves computer storage capacity. The more that data are used for training, the more precise will be the assignment of an unknown object to one of the predefined patterns. This self-learning capacity increases the flexibility significantly, and diffuse, possibly small but characteristic variance in the spectra can be recognized correctly, and systematic errors in measurements such as noise, bad baselines and so on are trained and will be recognized during the evaluation process, and may thus help to avoid misinterpretations. Unlike cluster analysis, ANN needs the data set to be divided into a training and a test data set. The training should be performed on a representative random sampling of the data population. In order to estimate how effectively the ANN works, the stringent “leave-one-out” cross-validation method may be used. Here, validation is performed on the basis of \(n - 1\) of the cases (spectra) investigated and the one case left out is tested (reclassified).

### 6 APPLICATIONS

#### 6.1 Characterization of Particular Cell Compounds and Structures

This section describes the characterization of particular cell components identified and analyzed by specific vibrational bands. In this context resolution enhancement techniques and/or difference spectroscopy are of particular help in identifying compound-specific vibrational
features. IR spectra from a number of microorganisms exhibit characteristic IR bands of variable intensities that cannot be considered to be spectral variations because of experimental conditions or changes in microbiological parameters. A detailed analysis of these spectral features revealed the presence of particular cell constituents such as intracellularly accumulated storage materials, endospores, and cell surface structures like proteinaceous and polysaccharidal capsules, or the detection of metabolically released CO₂ in cells and cell cultures.\(^{(19, 27–29)}\)

6.1.1 Cell Storage Materials

Poly-β-hydroxy fatty acids (PHFs), to give an example, are energy and carbon reserve compounds found in many prokaryotes. Generally PHFs are accumulated under the limitation of nutrients when supply of energy and carbon is in excess. Under conditions of starvation, PHFs can be utilized and degraded by the microorganisms helping the cells to survive under severe starvation conditions. It is known that the survival rate is related to the amount of PHFs, which are intracellularly accumulated as small granules. These granules can easily be detected by a light microscope or by electron microscopy (marked by G in Figure 11a). Poly-β-hydroxybutyrate (PHB), to give an example, is frequently found in bacteria (e.g. various strains of Bacilli, Clostridia, Acetobacter, Legionella, and Pseudomonas). In most microbial IR spectra the ester carbonyl band at 1738 cm\(^{-1}\) is only a small weakly expressed shoulder. This band is caused predominantly by the >C=O stretching vibration of ester-bound fatty acids, of the membrane-forming ester-bound lipids. Gram-negative bacteria generally show a stronger ester carbonyl band than the Gram-positive organisms owing to the presence of an additional membrane layer, the outer membrane. In spectra obtained from Legionella, Pseudomonas or Bacillus strains, for instance, a rather prominent ester >C=O stretching band, accompanied by a number of additional bands between 900 and 1500 cm\(^{-1}\), is occasionally observed which is not permanently present throughout the cell cycle. For some Legionella pneumophila strains this band reaches a maximum of intensity after 48 h, while at 120 h of growth practically no additional >C=O ester band can be detected. Figure 11(b) shows the overlaid FTIR spectra of L. pneumophila strain RKI/II8 grown for 48 (curve A) and 120 h (curve B), respectively. Inspection of the two spectra reveals characteristic differences, most prominent in the ester carbonyl stretching region around 1740 cm\(^{-1}\). Figure 11(c) gives the difference spectrum as calculated from A and B. This difference spectrum closely resembles the FTIR spectrum recorded from isolated and purified PHB. At least ten bands can be identified and are assigned to a typical polyester compound. The quantitative determination of PHB is achieved by calculation of the ratio \(\alpha = I_1/I_2\) (see Figure 11b), where \(I_1\) is the intensity of the ester carbonyl peak at 1738 cm\(^{-1}\) used as a measure marker band of PHB content, and \(I_2\) is the intensity of the amide II peak at 1550 cm\(^{-1}\) used as an internal standard which measures approximate total cell mass.

6.1.2 Endospore Formation in Cells

Spore formation in bacteria serves as a strategy for survival under unfavorable conditions. Endospores are resistant to heat, radiation and chemicals, and can
survive starvation. In contrast, vegetative cells spores are not killed by standard sterilization techniques and can cause severe medical problems. The multistage transformation process that occurs within the mother cell has been investigated thoroughly by a variety of molecular genetic, analytical and structural techniques. FTIR spectroscopy can be used to monitor the multiphase process of sporulation, avoiding or complementing more time-consuming procedures like staining, microscopic enumeration and isolation.

The IR spectra of some strains of bacilli and clostridia exhibited some relatively weak extra bands around 1279 cm\(^{-1}\), 767 cm\(^{-1}\), 728 cm\(^{-1}\), 703 cm\(^{-1}\), and 660 cm\(^{-1}\) (see Figure 12). Calculation of the difference spectra reveals prominent bands between 1650 cm\(^{-1}\) and 1250 cm\(^{-1}\). Light microscopic examination of the same suspensions used for FTIR spectroscopy reveals up to 50% free and mature endospores. Five of the ten most intensive bands of the difference spectrum depicted in Figure 12 are diagnostic for dipicolinic acid (DPA), a compound involved in sporulation. The strong \(>\text{C}=\text{O}\) stretching band of COOH of DPA (expected to be around 1705 cm\(^{-1}\)) cannot be discovered in the difference spectra, since chelate binding of Ca\(^{2+}\) ions in vivo results in the two stretching vibration bands of the COO\(^{-}\) group at \(\sim1605\text{ cm}^{-1}\) and \(1405\text{ cm}^{-1}\), respectively. A large proportion of the spore-coat is composed of polypeptides. It is very interesting that the amide I and amide II bands are not found to be increased in spectra from sporulating cells. This is probably because the total amount of protein roughly remains unchanged. It is anticipated that the effect of antibacterial agents on sporulating cells can be accessed quantitatively by calculation of appropriate band ratios, for example the ratio of 1279 cm\(^{-1}\) (marker band) and 1545 cm\(^{-1}\) (amide II band).

6.1.3 Metabolically Released CO\(_2\)

The detection and quantitation of metabolically released CO\(_2\) in bacteria and yeasts is an additionally interesting aspect of the FTIR technique. Carbon dioxide provided intracellularly or elsewhere, which is usually detected as CO\(_2\) hydrates in water, can be determined extremely sensitively, since the CO\(_2\) band near 2343 cm\(^{-1}\) is present in a spectral region where signal-to-noise ratio is optimal and which is usually devoid of overlapping spectral features of the biological material. Figure 13(a) shows the spectra of a fully hydrated sample of a Candida dubliniensis isolate (1), of pure water (2), and the difference spectrum 1 minus 2 (3). In the spectral region between 2400 and 2300 cm\(^{-1}\), the asymmetric stretching band of CO\(_2\) hydrates can be detected near 2343 cm\(^{-1}\). Apparently, the CO\(_2\) band monitors distinct levels of metabolic activity in the cells or within the culture. Figure 13(b) shows two series of IR spectra obtained from yeast cultures of Issatchenkia occidentalis differing in supplementation, with glucose as a substrate for CO\(_2\) production. Spectra are collected as a function of time in intervals of 8 min after addition of glucose to the yeast culture. A control culture without glucose is measured identically. Using the integral intensity of the peak at 2343 cm\(^{-1}\) to quantify CO\(_2\) evolution, the kinetics of CO\(_2\) release after addition of various different substrates to a yeast culture can be sensitively monitored (Figure 13c). Provided that \(^{13}\text{C}\)-labeled substrates are available, the simultaneous detection of the kinetics of CO\(_2\) production from two different substrates can be determined as well, since the \(^{13}\text{CO}_2\)-peak is detected near 2277 cm\(^{-1}\), quite separate from the \(^{12}\text{CO}_2\) stretching band near 2343 cm\(^{-1}\).

6.2 Differentiation, Classification, and Identification of Microorganisms by Infrared Spectroscopy

More than 3000 bacterial species have been named systematically with each species comprising 5–1000

---

**Figure 12** IR spectra of Clostridium sordelli (strain DSMZ (Deutsche Sammlung von Mikroorganism und Zellkulturen) 44) which may produce different amounts of endospore as a function of growth time. Spectra were obtained from two populations grown for 48 h (A) and 24 h (B) on Columbia blood agar plates at 37 °C, respectively. The difference spectrum (A) minus (B) is shown by curve (C). Data acquisition parameters, see legend to Figure 5. (This figure has been adapted from Naumann et al.)

---
strains also described by strain numbers (corresponding numbers for yeasts and fungi are not yet available). Many have been described as human, plant or animal pathogenic which emphasizes that most efforts devoted to the isolation and characterization of microorganisms to date are related to the problem of host–cell interaction. Probably there are a million or even more different bacterial species on earth which have not yet been recognized. Taxa, such as families, genera, species, and strains are defined as groups of related microorganisms comprising different levels of discrimination. Modern methods used in microbial taxonomy in addition to classical microscopy, staining techniques, biochemical or enzyme reaction patterns are molecular genetic techniques.

Microbial diversity is always structural and biochemical diversity. IR spectroscopy on intact microorganisms provides information on the structure and composition of the whole cell. Figure 14 shows three typical MIR spectra of microbial samples, a Gram-positive \textit{Staphylococcus aureus}, strain ATCC 6538, Gram-negative \textit{Pseudomonas aeruginosa}, strain ATCC 27853, and yeast \textit{Candida albicans}, strain ATCC 10231 isolate, each dehydrated to a thin film disc on a ZnSe optical plate and measured with the multicuvette system shown in Figure 6(a). While spectrum 3 differs significantly from 1 and 2, the latter two are seemingly similar. However, a more detailed analysis of these two spectra by focusing on selected spectral regions and calculating second derivatives proves the presence of distinct spectral differences between these microorganisms as well (see Figure 14).

Because microbial IR spectra are complex spectroscopic signals encoding the superposition of hundreds or even thousands of bands that cannot be resolved by any means, pattern recognition techniques have to be used which consider the spectra as fingerprints rather than a combination of discrete band intensities, frequencies and bandwidths. Figure 15 shows two dendrograms obtained by hierarchical cluster analysis performed on IR spectra.
obtained from very diverse microorganisms. It is particularly interesting that the IR technique is not restricted to the analysis of bacteria. Yeasts and fungi can also be analyzed. Figure 15(a) gives the dendrogram of a hierarchical classification trial based on approximately 240 microbial IR spectra obtained from independent measurements on 13 different strains of Gram-positive and Gram-negative bacteria and of 87 spectra from 29 strains of six different Candida species. Three main clusters are recognized, which discriminate perfectly between the Gram-positive and Gram-negative bacteria on the one hand, and the yeast strains on the other hand. A closer inspection of the fine structure of the dendrogram shown in Figure 15(a) reveals a perfect discrimination at the species level, as established by molecular genetic techniques. Figure 15(b) shows the result of a separate cluster analysis performed on the different species and strains of Candida only using a different set of spectral regions as input for cluster analysis. This dendrogram proves that Candida species can be perfectly classified at species level by IR spectroscopy. As all cell components depend on the expression of smaller or larger parts of the genome, the FTIR spectra of microorganisms display specifically a complete phenetic and a genetic fingerprint of the cells under study. This is why the specificity of the technique is very high, allowing differentiations at quite different taxonomic levels, even down to the subspecies, strain and/or serogroup/serotype level. The latter is demonstrated by the FTIR-based classification of different isolates of Escherichia coli and some strains of S. aureus. Figure 16(a) gives the dendrogram of a classification trial on a selection of serologically different E. coli strains. The purpose of this analysis was to group the spectra of the isolates according to their O-antigenic structure. O-antigenicity is usually determined by serological and sodium dodecyl sulfate–gel electrophoretic techniques. The O-antigenic epitopes are structurally determined by the O-specific side chains of the LPS which are complex heterooligosaccharide compounds. Therefore, these structures are primarily observed in the spectral region between 700 and 1200 cm\(^{-1}\), where the carbohydrates dominate the
spectral features observed. Using Ward’s algorithm for cluster analysis, three main clusters are obtained which perfectly correspond to the O 18, O 25, and O 114 group related to methicillin resistance of these organisms. Results of cluster analysis corroborate that differentiations can be obtained even at the strain level.

Different algorithms can be used to identify unknown microbial strains on the basis of a reference database. It is pertinent that these reference data sets contain representative numbers of spectra covering all relevant spectral types to be identified. Unknown microbial samples will only be correctly identified with validated spectral types to be identified. Unknown microbial strains of different species and strains of Staphylococci, Enterobacteriaceae, Pseudomonas, Bacilli, Clostridia and yeasts. IR identification data sets are also available for a spectroscopic Gram test and for the identification of waterborne microorganisms.

Identification libraries based on ANN analysis in combination with feature extraction methodologies are used to identify unknown microorganisms. The elaboration of such ANN libraries is divided into several steps including data pretreatment, normalization of data, spectral feature extraction, elaboration of adequate network architectures, training functions, and learning parameters.

Figure 15  Dendrogram of a hierarchical cluster analysis performed on 240 spectra of different strains of Gram-positive and Gram-negative bacteria, and of yeasts belonging to the genus Candida. Correlation with the database. An already tested algorithm is based on the calculation of differentiation indices (\(D\) values). The spectrum is first subdivided into several spectral windows, selected such that they contain the most discriminative spectral information. The combination of these spectral windows is then used in a stepwise correlation procedure to determine the most similar spectrum contained in the database. Finally a list of most probable hits is reported by the program. The Pearson’s correlation coefficient (\(D\) values, see Equation 2) was used to calculate the distance matrix. Further experimental and data evaluation parameters, see legends to Figures 5 and 10.
The most important idea in this approach is first to establish optimized ANN libraries for subgroups of the whole reference library and then to connect them in the form of a multilayered neural architecture. The user working with such libraries can solve complicated identification problems by running through all layers (neural networks of subgroups) of these reference databases in a controlled multistack procedure. The information flux is controlled by one heading network whose single task is to separate, for example, Gram-positive and Gram-negative bacteria, yeasts, and a number of different genera. In this way a microbial IR identification library is available that comprises six different bacterial genera each containing a representative number of species and strains within the genera *Pseudomonas*, *Bacillus*, *Staphylococcus*, *Streptococcus*, *Aeromonas*, *Mycobacteria* and two subnets for the identification of different *Candida* species and for differentiation between fluconazole-sensitive and fluconazole-resistant *C. albicans* strains, respectively.\(^{133}\)

### 6.3 Sensitivity Testing by Infrared Spectroscopy

One important additional item of clinical microbiology is antibiotic susceptibility testing. The procedures that have been elaborated for practice are generally based on photometric determination of bacterial growth by light transmission/absorption (optical density) or light scattering (nephelometry). Some promising physical techniques such as radiometry, microcalorimetry, bioluminescence and electrical impedance have not yet reached the stage of general application. IR spectroscopy is also useful in this field, since quantitation of cell mass as a function of antibiotic treatment, as well as the detection of antibiotic-induced structural changes in microbial cells, is well within reach of sensitivity and specificity of IR spectroscopy.\(^{6,34,35}\) A simple and rapid sampling technique has been elaborated for the detection of time-dependent variations within bacterial cells grown in liquid cultures.\(^{6}\) A typical protocol of this technique includes the following steps: aliquots of the control and the treated liquid cultures are centrifuged, the cells are washed once or twice, and are again pelleted. The pellet is then quantitatively transferred to an IR transparent plate suitable for A/T-measurement (see Figure 6a).

The principles of this technique can be derived from Figure 17 which compares the spectral information obtained from measurements on a control and on a chloramphenicol-treated culture. Most of the bands have been adapted from Helm et al.\(^{17}\)

---

**Figure 16** Spectral typing of closely related microorganisms. (a) Clinical isolates of *E. coli* (numbers in right column) belonging to different serogroups: O 25, O 18, and O 114 according to their O-antigenic structure. (b) Isogenic strains of *S. aureus* (numbers in right column) differing only in respect of a number of genetic changes influencing methicillin resistance. Hierarchical clustering was achieved applying the Ward’s algorithm and using the Pearson’s correlation coefficient as the distance measure \((D \text{ values according to Equation 2)}\).\(^{17,18}\) The first derivatives of the spectra considering the spectral ranges 700–900 and 900–1200 cm\(^{-1}\) \((a)\) and 900–1200 cm\(^{-1}\) \((b)\) were used, respectively. For further experimental parameters, see legends to Figures 5 and 10. (This figure has been adapted from Helm et al.\(^{17}\).)
Figure 17 IR bands useful for antibiotic susceptibility testing. 
(a) Assignment of six IR peaks selected from the second derivative spectrum of *S. aureus* (strain SG 511) sampled from the logarithmic phase of growth: (1) \( \geq C=O \) ester stretching near 1740 cm\(^{-1}\); (2) tyrosine band near 1516 cm\(^{-1}\); (3) \( \geq CH_2 \) scissoring band of fatty acids near 1467 cm\(^{-1}\); (4) \( \equiv COO^- \) symmetric stretching near 1400 cm\(^{-1}\); (5) \( \equiv PO_2^- \) asymmetric stretching frequency, for example of \( \equiv PO_2^- \) phosphodiester functional groups, near 1245 cm\(^{-1}\); (6) most intensive band of the sugar ring vibrations near 1085 cm\(^{-1}\). (b) Mean change \( \Delta P \) of peak heights (in arbitrary units) of the six selected IR bands shown in (a) after 30 min of growth of a control culture of *S. aureus* (strain SG 511) (open bars) in comparison to the corresponding \( \Delta P \) values of a culture treated with 20 \( \mu g \) mL\(^{-1}\) of the protein biosynthesis inhibitor chloramphenicol (black bars). (Adapted from Naumann.\(^6\))

shown in Figure 17(a) respond sensitively to antibiotic-induced changes and can thus be used to test drug–cell interaction. Some of them reveal considerably reduced relative peak intensities compared to the control (see Figure 17b). Peaks 5 and 6, assigned to components of the cell wall, in contrast, show increased intensities. This is explained by the reaction mechanism of chloramphenicol (a protein biosynthesis inhibitor), which at this early stage of cell–drug interaction inhibits cell division but not yet cell-wall synthesis. Thus, the analysis of drug-induced changes in bacterial cells is feasible using specific IR marker bands (in case of a protein synthesis inhibitor, for example, the various amide bands). The time of growth, after application of the antibiotic, needed to detect specific changes in the culture can be as little as 30 min.
In some cases, testing for resistance or sensitivity against antimicrobial drugs by IR spectroscopy is possible on the basis of the spectral information alone, i.e. without any application of the antibiotic. This is feasible where the causes and mechanisms of resistance reside somewhere in the cell wall’s or in the membrane’s altered structure. Figure 18(a) gives an example on seven C. albicans strains (clinical isolates) that were known by other techniques to be sensitive and seven strains that were highly resistant to the antifungal azole derivative fluconazole. The cluster analysis performed on these strains provides a classification scheme that separates the strains into two distinct groups quite well according to what is known a priori. This successful classification could only be obtained by using a few rather narrow spectral ranges that were identified, e.g. by trial and error or by using linear discriminant analysis (see Figure 18b).

6.4 Detection, Enumeration, and Identification of Microcolonies

The light microscope has long been a standard analytical instrument in almost all microbiological research and routine laboratories. While light microscopes provide information on shape, color, and contrast of a given sample, IR spectroscopy may give information about structure and identity of complex samples at the molecular level. Thus, the combination of light microscopy with the sensitivity and specificity of IR spectroscopy provides considerable additional information, in particular the possibility of obtaining structure information on “what you see”. With the development of modern FTIR spectrometers and increased sensitivities of small detector elements, the coupling of an IR spectrometer to a light microscope was much improved and high quality “FTIR microscopes” appeared on the market. This combination pushed the detection limit down to the subnanogram level and opened up the field of spatial resolution and imaging to IR spectroscopy. Because the conventional light microscope uses condensers and objective materials that have limited transparency for IR radiation, the FTIR microscope generally requires all-reflecting optical devices, so-called cassegrainian optics. An assortment of apertures placed in the plane of the real intermediate image of the sample is used to mask the sample areas of interest down to the 10-µm spot of spatial resolution, close to the value restricted by the wavelength of the IR light used.\(^{56}\)

The microbiological characterization of unknown clinical, food, water, or airborne microbial specimens includes the fundamental steps of detection, enumeration, and differentiation of cells. Different techniques are used to detect, count, and differentiate microorganisms. These techniques include counting colony-forming units, measurement of optical density, use of cell counters or cell sorters and application of a whole arsenal of techniques by which microbial cells can be differentiated including molecular genetic methodologies.

Some fundamental efforts have been made to integrate detection, enumeration, and identification in one single instrument using IR microspectrometry.\(^6\) When applying IR microscopy to microbial samples, three questions have to be addressed: (1) what are the real detection limits for microorganisms? (2) how can nanogram amounts of microorganisms be sampled and reproducibly measured by the spectrometer? and (3) can detection, enumeration, and differentiation of microorganisms be achieved by combining optical, spectroscopic and computer imaging techniques? The sensitivity of a standard IR microscopic instrumentation is demonstrated in Figure 19 which shows IR spectra obtained from three different microbial spots of a given uniform bacterial biofilm dried down to a BaF\(_2\) optical plate. From the diameter and the film thickness of the spots, the number of bacterial cells detected by the IR beam can be estimated to be of the order of \(10^4\) (spectrum 1, 80-µm spot), \(10^3\) (spectrum 2, 40-µm spot) and \(10^2\) (spectrum 3, 20-µm spot), respectively.

Figure 19 Sensitivity test for a standard FTIR microscope. Spectra shown represent the IR signals from microcolonies containing approximately \(1-5\times10^5\) cells (spectrum 1), \(1-5\times10^3\) cells (spectrum 2), and \(1-5\times10^2\) cells (spectrum 3) using 80, 40, and 20-µm apertures, respectively. Dried colony spots of E. coli (strain RK1 A139) deposited on a round BaF\(_2\) plate (Ø 25 mm) were measured. The spots were obtained by the stamping technique described in the text. Technique: A/T; number of scans applied: 512; nominal physical resolution: 6 cm\(^{-1}\); apodization function: Blackman-Harris, three-term; FTIR microscope: IRScope I coupled to an IFS 28/B spectrometer (Bruker Optics, Germany); note that signal-to-noise ratios were calculated for the first derivatives with the signal determined at 1600–1700 cm\(^{-1}\) (amide I band), and the noise (peak-to-peak) between 2000 and 2100 cm\(^{-1}\).
Figure 20 Detection, differentiation, and classification of different microbial microcolonies. (a) Micrograph (magnification approximately 200×) of three different colony spots deposited on BaF₂ windows by the stamping technique described. (b) FTIR species of the microcolonies shown in (a). (c) Hierarchical cluster analysis and (d) factor analysis performed on IR measurements of approximately 30 different colony spots. The groupings suggested by hierarchical clustering are: C₁ = S. aureus (strain RKI/WG PS42D); C₂ = Streptococcus faecalis (strain DSMZ 20371); C₃ = E. coli (strain RKI A139). For instrumental and data acquisition parameters, see legend to Figure 19.

To sample microbial cells for FTIR microscopic measurements, the following experimental protocol has been established. Aliquots of the microbial cell suspension, sufficiently diluted to guarantee single colony growth on solid agar plates, are plated and incubated over a period of 6–8 h. After these growing times, colony-forming units are generally not yet visible to the naked eye. Round IR transparent plates made from BaF₂, CaF₂ or ZnSe are then gently pressed to the agar surface. This imprinting technique transfers spatially accurate small amounts of the microcolonies (two to three microbial layers) on to the plate and provides replica of dried and round microbial colony spots that can be measured by the FTIR microscope. With the aid of a computer-controlled x,y-stage these spots are measured automatically or operator-controlled using video techniques. Additionally, the number of colony spots can be counted and size classification of these spots is also possible.

Figure 20 gives an example of IR microscope measurements performed on a mixed culture of three different microorganisms, namely S. aureus, Streptococcus faecalis and E. coli. Figure 20(a), upper panel, shows the micrograph from a selected area of the colony replica, which shows three different microcolonies that can
already be morphologically differentiated by eyes. Typical spectra obtained from these three colony spots are shown in the lower panel of Figure 20(a). These spectra immediately suggest that the three microcolony imprints have indeed been derived from three different microorganisms. The next steps in analysis include (1) representative sampling of FTIR microscopic spectra of bacterial film spots, which (2) are then subjected to MSA. Figure 20(b) and (c) show typical results when using hierarchical clustering (Figure 2b) and factor analysis (Figure 2c). Both evaluation techniques unequivocally prove that the spectra obtained from the microcolonies are indeed characteristic of three different microorganisms present in a mixed culture.

7 PERSPECTIVES

The main advantages of IR spectroscopy which make it attractive are extreme rapidity compared to conventional techniques, uniform applicability to diverse microorganisms, and a high specificity which allows differentiation even down to subspecies levels. The IR methodology requires only low amounts of consumables, it is computer compatible, and may thus promote exchange of results and databases via data nets. The strength of the IR technique is its ability to conduct epidemiological case studies and large screening experiments very quickly. Additional fields of application are the detection of infection chains and the control of therapy, the maintenance of strain collections, and the differentiation of microorganisms from the environment for which established systems are not yet available. In the food, water, and pharmaceutical industries IR spectroscopy may contribute to improve microbiological quality control. For the control of biotechnological processes it is an alternative or additional technique to already existing analytical tools. Drawing upon the knowledge obtained to date, the serial type of a dedicated instrument for IR characterizations of microorganisms is now available from an IR spectrometer producing company. The prospects for the use of FTIR microscopy for microbiological characterization are very promising. This new technology may help to scale down the number of cells needed to a few hundred, to analyze mixed cultures, and to detect light-microscopic and spectroscopic features of microorganisms simultaneously. The development of a fully automated IR spectroscopic system of microbiological analysis that combines detection, enumeration, and identification of microorganisms is already being addressed. The sampling techniques, spectroscopic procedures, and data evaluation strategies elaborated in the context of microbiological IR spectroscopy can easily be carried over to characterize other microorganisms such as amoebae and viruses, and even plant or mammalian cells and tissues. Information density can be increased by combining the spectral traits accessible from the NIR, MIR, and FIR regions of the electromagnetic spectrum and by using IR and Raman spectroscopy in tandem. IR and FT-NIR Raman spectra of nearly identical samples of intact microorganisms can now be obtained with excellent reproducibilities. This makes it possible for the first time to establish a combined use of IR and Raman spectroscopy of complex biological samples, which constantly and notoriously give Raman spectra that are overwhelmed by the fluorescence background using laser excitation in the visible region. The exploitation of the complementarity of IR and Raman spectroscopy particularly may open up new avenues for biomedical applications in the future. A particularly intriguing challenge is to elaborate computer-based and user-friendly pattern-recognition software which gives data reduction, effective feature extraction, and optimal classification results useful for practical purposes collected in the NIR, MIR, and FIR, or by combining the two vibrational spectroscopic techniques of IR and Raman spectroscopy.

1 Introduction

IR spectroscopy provides information relating to the vibration of covalent bonds within molecules. The wavelength of light absorbed by a vibrating bond depends upon the atoms in the bond, the type of bond, the type of vibration and any inter- and intramolecular interactions. For complex samples such as human tissues, an IR spectrum therefore provides a direct indication of sample biochemistry. With the correct choice of sampling methodology (usually an IR microscope) information on the biochemical nature of disease states can be obtained from tissue samples, which can often be useful diagnostically. Variations in spectral signatures arising from nucleic acids, proteins and lipids can provide important information in a number of disease states, including Alzheimer’s disease (AD), breast cancer and skin cancer.

The information obtained by IR spectroscopy is difficult to obtain with many other instrumental techniques. For example the signal-to-noise ratio obtained by IR microscopy is far superior to that seen with Raman methods, allowing more sophisticated data processing and so more information to be extracted. Furthermore, many species of interest cannot be studied in situ with other techniques. Nucleic acids are a case in point. Powerful techniques such as nuclear magnetic resonance spectroscopy provide no information concerning this material, while Raman techniques only provide information relating to individual nucleotides. In contrast, DNA and RNA give rise to IR signatures that provide information relating to nucleic acid content/structure.

To appreciate fully the information contained in the complex spectra obtained from human tissues and cells, a unique combination of expertise in spectroscopy, biochemistry and anatomy/histology is required. This combination allows the investigator to avoid potential artefacts due to incorrect sampling and spatial variations in sample composition and to attribute the major absorptions present in spectra to individual biochemical species. However, spectral interpretation is often a highly subjective process, a fact that is made worse when one considers that many thousands of spectra are often acquired from a single tissue section. The application of pattern recognition techniques to IR data removes this subjectivity and allows realistic processing of these large data sets. In addition, many new methods are being developed which allow presentation of these complex data sets in a form readily interpreted by the nonexpert.

1 INTRODUCTION

IR spectroscopy provides information relating to the vibration of covalent bonds within molecules. The wavelength of light absorbed by a vibrating bond depends upon the atoms in the bond, the type of bond, the type of vibration and any inter- and intramolecular interactions, while the intensity of light absorption is directly related (by the Beer–Lambert law) to the concentration of molecules containing the bond. The IR spectrum of a material therefore provides information relating to the quantity, composition, structure and environment of materials in a sample. Furthermore, IR spectroscopy provides this information for all IR active materials present in a sample simultaneously. For complex samples such as human tissues an IR spectrum therefore provides a direct indication of sample biochemistry.¹⁻³

Any method that is able to provide information relating to tissue biochemistry can also be used to study and diagnose disease states. This arises from the fact that all disease states are accompanied/ caused by alterations in tissue biochemistry. These alterations in tissue biochemistry will result in changes in the IR spectrum of the tissue. A comparison of the spectra
of healthy and diseased tissues should therefore provide information that can be used to determine the presence of disease and also to understand the disease at the molecular level.\(^4\)\(^–\)\(^6\)

IR spectroscopy has a number of advantages over other instrumental methods for the analysis of tissues including speed, sensitivity, flexibility and low cost. Sampling techniques exist to ensure that spectra can be obtained from any type of biological sample, and high-quality spectra may be obtained within minutes on compact low-cost instruments. In addition, no endogenous chromophores (which may potentially perturb the system under investigation) are required. One obvious drawback is the requirement for tissue to be removed from subjects before analysis. However, as biopsies are routinely taken for many pathological conditions, obtaining samples is generally not problematic.

2 EXPERIMENTAL ASPECTS

With all instrumental techniques, determining the most appropriate manner in which to make measurements is one of the most critical steps. Inadequate experimental design may lead to no results, or worse, to misleading results. For example, for many years biophysical studies of proteins and peptides were carried out using organic solvents such as trifluoroethanol (TFE) or dimethylsulfoxide (DMSO).\(^7\)\(^,\)\(^8\) The rationale for the use of these solvents was that their organic nature allowed them to serve as membrane mimetic agents, thus allowing studies of peptides in a “membrane-like” environment without the membrane (a necessity for nuclear magnetic resonance studies). Typically such studies found that peptides and proteins dissolved in TFE adopted a helical configuration, a finding taken to indicate that in a cell membrane such peptides would adopt a helical configuration. In contrast, peptides dissolved in DMSO were found to be unstructured. However, IR spectroscopic studies have since demonstrated that all peptides and proteins, regardless of native structure, adopt helical configurations in TFE and are unstructured in DMSO. Conclusions drawn concerning native structures of peptides dissolved in DMSO and TFE reflect the experimental design rather than inherent properties of the peptides and proteins and must therefore be treated with caution.

Clearly the complex nature of human tissues requires great care to be taken in designing experiments for the ex vivo analysis of tissues and body fluids by IR spectroscopy. In determining the most appropriate manner in which to make measurements one must consider the range of sampling techniques available, the form of the sample, the nature of the sample, the stability of the sample and the nature of any possible interferents.

2.1 Sampling Techniques

IR spectroscopy is not limited by the physical state of the material under investigation. Methodologies exist which allow spectra to be obtained from solids (e.g. bone, teeth), liquids (e.g. amniotic fluid, slurries (e.g. feces) and particulate suspensions (e.g. blood). However, it should be stressed that care is required in determining the optimal sampling method to be used, perhaps more so in the case of cells, biofluids and tissues than for other types of samples. The complexity of cells, biofluids and tissues present unique challenges to the IR spectroscopist, and these complexities often dictate the choice of sampling technique.

2.1.1 Sampling Techniques for Liquids

Many body fluids are important sources of diagnostic information in medicine, including amniotic fluid, synovial fluid, sweat, urine and blood. Fluid samples are most readily analyzed using transmission techniques. A small volume (typically 5–10 \(\mu\)L) of sample is placed between IR-transparent substrates separated by a thin spacer to provide a reproducible pathlength. It should be stressed that the strength of the absorption bands of water which are seen in the mid-IR region of the spectrum is such that with even moderately thick samples, total absorption of the IR light may occur at a broad range of wavelengths.\(^9\)

In general, for biological fluids the pathlength should be kept to 10 \(\mu\)m or less for measurements in the mid-IR. For measurements in the near-IR region of the spectrum, the pathlength may be much greater due to the reduced intensity of the overtone and combination absorptions from water found in this spectral region. In fact extended pathlengths (0.1–1 mm) are not only possible but a necessity in near-IR studies, owing to the reduced intensity of the overtone and combination absorptions of the analytes of interest in the near-IR compared to the fundamentals observed in mid-IR spectra.

In addition to allowing longer pathlengths to be used, near-IR spectroscopy has the additional advantage that spectra are generally simpler than mid-IR spectra. Typically only overtones and combination absorptions arising from vibrations of C–H, N–H and O–H groups are seen in near-IR spectra. This may facilitate identification of species of interest in the absence of absorptions from confounding species. However, it should be borne in mind that this reduced complexity of near-IR spectra also means a reduced information content. For example near-IR spectra do not provide information relating to phosphate or carbonyl groups. When deciding whether to acquire mid- or near-IR spectra, the nature of the information sought should therefore guide the choice.

The analysis of biological fluids by recording transmission spectra from films prepared by drying the fluid on to an IR-transparent substrate is gaining popularity.\(^9\)
INFRARED SPECTROSCOPY, EX VIVO TISSUE ANALYSIS BY

Figure 1 Functional group maps showing the distribution of protein (integrated amide I intensity) within two dry films of amniotic fluid (a) and (c) and cross-sections showing the intensity through the center of the films (b) and (d).

This method has the advantages that the strong interfering absorptions from water are removed and the sample becomes more stable when dried. It should be stressed that any volatile materials present in the sample will be lost upon drying. In addition any information relating to perturbation of the structure of water by analytes in the sample and information relating to hydration is lost.

Investigators should be aware that artifacts associated with heterogeneity of the film upon drying may cause significant problems. For instance, it is possible that upon drying preferential interactions occur between some solutes such that they co-deposit. Alternatively, formation of microdomains of relatively apolar materials may exclude polar material from these areas of the film. In addition, each of the materials present will have a different solubility in the bulk fluid, and so may be deposited at different rates as the fluid dries. IR microscopic studies of films prepared by drying amniotic fluid on to calcium fluoride windows show significant heterogeneity in solute deposition. Functional group mapping (see section 6.1) allows the distribution of protein in dry films to be monitored. The distribution of protein in two amniotic fluid films is shown in Figure 1(a) and (c). Clearly, deposition of protein is not uniform but is concentrated at the edges of the films, most likely as a result of capillary flow during drying. In some films the situation was complicated by the formation of two concentric rings. The reason for the appearance of this second ring is not clear, but it may be related to the rate of drying or surface properties of the window. Additional rings were also seen in the region of air bubbles that formed during drying.

This sample heterogeneity has important repercussions. Variations in the distribution of photons within the IR beam of the spectrometer can potentially have significant effects upon experimental results, due to variations in the area of the film sampled. Similarly, positioning of the sample within the sample compartment will be crucial. Such factors are of particular significance when working with more than one spectrometer and will have a significant impact upon data transferability. To avoid large variations in the distribution of solutes when preparing
films, substrates should be cleaned thoroughly (preferably with a plasma cleaner) before deposition of the film, the fluid should be degassed to prevent formation of bubbles and the film should be dried rapidly under high vacuum. While these precautions will not prevent capillary flow and the formation of a ring of solute at the edge of the film, it will prevent formation of a second, concentric ring or smaller rings formed by air bubbles. It should also be stressed that the fluid viscosity will affect capillary flow and the extent of solute deposition at the edges of films may vary with different types of fluid.

2.1.2 Sampling Techniques for Solids

2.1.2.1 Macroscopic Sampling  Techniques for obtaining spectra from macroscopic solid materials include standard transmission, attenuated total reflectance (ATR) and photoacoustic spectroscopy. Each technique has advantages and limitations. Transmission techniques are the simplest available for acquiring spectra of solid materials. Traditional methods of spectral acquisition involve either dispersion of the sample in KBr that is then compressed to form a disk or mounting of the sample directly on an IR-transparent substrate. While dispersion of the sample in KBr is straightforward, it does require the sample to be in powder form. This requires that the sample is physically robust. Obviously, most tissues cannot be analyzed in this fashion. Samples that may be analyzed in this way include calcified tissues such as bone and tooth enamel. However, it should be borne in mind that the process of grinding the sample to form a powder may result in alterations in crystallinity of the mineral matrix in such samples.

Mounting samples on or between IR-transparent substrates is more generally applicable to studies of tissues. However, the strength of the absorption bands seen in the mid-IR region of the spectrum is such that with even relatively thin samples, total absorption of the IR light may occur. In general, for samples containing significant quantities of water, sample thickness should be kept to 10 µm or less. In practice this may be achieved in two ways. For tissues, the simplest method of preparing samples to minimize the pathlength is to compress a small piece of tissue between IR-transparent windows. The windows are generally composed of CaF$_2$ or BaF$_2$. To ensure that reproducible pathlengths are obtained, one window may be etched with a 5–10-µm depression. Unfortunately, this simple procedure cannot be used for all samples. Some tissues, such as muscle tissue, cannot be compressed easily between windows. For such samples, compression between diamond windows is required.

Rigid samples such as muscle tissue may also be analyzed by specialized ATR accessories such as the Split Pea developed by Harrick. This consists of a small hemispherical ATR element (typically a 1–2-mm diameter germanium element) on to which the sample is placed. The sample is then compressed against the element with an anvil of some type under reproducible pressure. IR light is then directed through the germanium element, penetrating the sample once and being reflected back into the element and directed towards the detector. While this approach allows samples to be analyzed rapidly, it suffers from the reduced signal-to-noise ratio common to ATR methods. In particular, the fact that the crystal allows only a single reflection into the sample contributes to a reduced signal-to-noise ratio.

The major drawback of these simple approaches to sampling is that the physical integrity of the sample is lost. It then becomes impossible to correlate spectroscopic information with the histology of the sample, a fundamental issue in the analysis of tissues. To maintain the physical integrity of the sample, sections of tissue can be produced with the aid of a cryotome. Thin sections (7–15 µm) are cut and allowed to air dry (which takes only a few seconds) on an IR-transparent substrate. Spectra are then acquired from the dry tissue. This approach has three immediate advantages. First, the interfering absorptions from tissue water are removed. Second, removal of water effectively fixes the sample and prevents degradation of tissue components. Finally, and perhaps most importantly, the sample can be stained following data acquisition. Microscopic analysis of the stained tissue then allows a direct correlation to be drawn between sample histology/composition and spectra.

Occasionally, samples cannot be conveniently prepared by microtomy. For example, bone requires either specialized equipment to prepare sections or must be demineralized. Demineralization is obviously to be avoided in IR spectroscopic studies of bone, as usually the mineral matrix is the component of interest. Similar problems exist when studying teeth. Photoacoustic spectroscopy may be used as an alternative sampling technique. Photoacoustic spectroscopy makes use of the fact that when samples absorb IR light, they undergo a small thermal expansion. In a sealed chamber, this expansion produces a pressure wave that can be detected by a sensitive microphone, and the signal from the microphone can be Fourier transformed to generate a spectrum of the sample. This technique is ideal for irregular samples such as teeth. Furthermore, with a step scan interferometer, depth profiling can be achieved by varying the modulation of the IR light.

2.1.2.2 Microscopic Sampling  The complexity of tissues limits the applicability of the measurements discussed above. Tissue heterogeneity is particularly problematic. An IR spectrum represents the sum of the spectra of all of the IR active materials present in the
region of tissue through which the IR light passes. While this “averaging” is undoubtedly an advantage (discrete probes for individual materials are not required) it may lead to significant problems for the investigator who does not appreciate the heterogeneous nature of tissues. The composition of all tissues varies both spatially and temporally. Temporal variation may arise due to cyclical variations in tissue composition (for example due to hormonal effects) or as a consequence of aging. Spatial variability arises due to the heterogeneous distribution of tissue components within a sample. This spatial variability is illustrated clearly in Figure 2, which shows a photomicrograph of a stained section of a skin tumor. The sample is clearly composed of a number of distinct tissues, including the epidermis, dermis, hair follicles, sebaceous glands and tumor. A spectrum of the entire section (a macroscopic spectrum) will therefore contain contributions from all of these tissues, weighted with respect to their relative proportions in the sample. Thus, spectral features arising from one or more of the other tissue components may mask spectral features characteristic of the tumor.

To obtain information relating to the spatial distribution of materials within sections and to obtain spectra of pure tissue components the technique of IR microscopy is used. In its most basic form, an IR microscope is a beam condenser that reduces the diameter of the IR beam, focusing the IR light on to a small area of sectioned tissue. This allows high-quality spectra to be obtained from extremely small samples (30 × 30µm). In fact, with the use of highly focused synchrotron radiation, spectra may be acquired from samples as small as 3 × 3µm. By coupling an IR microscope to a high-precision computer-controlled stage the automated collection of IR spectra at each position in a two-dimensional grid defined over the tissue section becomes possible. Information collected at each point (pixel) is combined to produce an IR spectroscopic map of the tissue section. More recently, IR focal plane array detectors have been coupled to step-scan interferometers equipped with IR microscopes. In this case, multiple detector elements enable spectra at each pixel to be collected simultaneously. The focal plane array detector method is much faster than the traditional mapping technique, but can suffer from poor signal-to-noise ratios below 1400 cm⁻¹, which to date has limited applicability. With both techniques the end result is the same; large spectral maps are collected containing thousands of spectra per map with enormous amounts of both spatial and spectral information.

While a wide variety of sampling methodologies exist, it is becoming increasingly clear that IR microscopy is the sampling technique of choice. The ability to obtain spectra nondestructively with high spatial resolution and precision allows extremely detailed studies of tissues to be undertaken. Again, the ability to stain samples subsequently and compare histological information and spectroscopic information provides a significant advantage. Given these advantages and the almost universal acceptance of IR microscopy as the measurement technique of choice, the following sections will focus predominantly on acquisition, processing and interpretation of microspectroscopic data.

### 2.2 Sample Stability: Fixation of Samples

In all studies involving biological materials, questions of sample degradation over time arise. Of particular importance in this respect is the degradation of tissues and fluids in the brief period immediately following removal from the body. In this period, cells continue to metabolize but metabolic fuels are not replaced. Cellular disturbances during this period may result in spectral changes that may be confused with alterations in biochemistry caused by disease processes. With cell suspensions and tissues, it is possible to prevent this degradation by fixation with preservatives such as formalin (an aqueous solution of formaldehyde) or 70% ethanol in water. However, common fixatives such as ethanol/water and formalin might be expected to exhibit strong IR absorptions, and thus themselves be potential sources of artifacts in spectra. Furthermore, these fixatives preserve tissue by inactivation of degradative enzymes, which may also introduce artifacts into spectra.

The effect of ethanol/water on spectra of cultured human melanoma cells dried 30 min after suspension in...
Figure 3  IR spectra of (a) cultured human melanoma cells dried from 70% ethanol in water, (b) cultured human melanoma cells dried from formalin solution, (c) a film prepared by drying formalin, (d) cultured human melanoma cells suspended in formalin, washed in saline and dried and (e) cultured human melanoma cells dried from saline.

70% ethanol is shown in Figure 3(a). It is immediately apparent that suspension of the cells in ethanol significantly alters the spectrum compared to suspension in isotonic saline (Figure 3e). Most noticeably, a pronounced shoulder is seen at 1625 cm\(^{-1}\), with a second shoulder apparent at 1680 cm\(^{-1}\). The appearance of such spectroscopic features is highly indicative of the formation of aggregates of protein molecules stabilized by intermolecular hydrogen bonding, and is typical of spectra of proteins in aqueous alcohol mixtures.\(^{7,8,15}\) This aggregation is a result of the disruption of intramolecular hydrogen bonds within protein molecules, resulting in large-scale protein denaturation. Presumably this protein denaturation and aggregation forms the basis for the fixative properties of alcohol.

The intensity of the absorptions at 1625 and 1680 cm\(^{-1}\) is time dependent, increasing with prolonged suspension in the alcohol due to continued penetration of the alcohol into the cells. Fixation with ethanol can also be seen to reduce the intensity of the ester C=O stretching vibration at 1740 cm\(^{-1}\), suggesting a decreased lipid content in ethanol-fixed cells. This reduction in lipid content reflects solubilization of membrane lipids by ethanol. Large-scale protein denaturation and delipidation obviously make ethanol unsuitable as a fixative for IR spectroscopic studies.

The spectrum of melanoma cells dried from neutral buffered formalin is shown in Figure 3(b). The characteristic absorptions associated with hydrogen bond-stabilized aggregates are not present in this spectrum, indicating that formalin fixation does not induce unfolding of proteins. This is consistent with the known mechanism of action of formalin, which is the promotion of methylene bridge formation between lysine side chains, leaving the structure of the proteins essentially intact. While drying of cells from formalin does not appear to have significant affects upon the major protein absorptions, it does result in the appearance of a series of new absorptions between 1000–1500 cm\(^{-1}\). Analysis of the spectrum of a film prepared by drying neutral buffered formalin (Figure 3c) suggests that these absorptions arise from formaldehyde. It may be thought surprising that formaldehyde, a gas, is retained upon drying of the formalin. However, it should be borne in mind that water, as water of hydration, can be trapped in the salt crystals that form during drying, and it is likely that the salt crystals will also contain traces of the formaldehyde which was dissolved in this water. These distinct absorptions are removed upon washing the cell suspension with isotonic saline before drying (Figure 3d), resulting in spectra essentially identical to those obtained from cells suspended in saline (Figure 3e). Thus, if fixation of samples is desired, then formalin should be the fixative of choice for the vibrational spectrosocist and samples should be rinsed thoroughly with isotonic saline prior to analysis.

2.3 Sample Preparation

2.3.1 Preparation of Cell Samples

Preparation of cell samples for IR spectroscopic analysis is relatively straightforward. In general, cells are usually studied as dry smears. As discussed above this has the advantage of halting all biochemical reactions within the cells, effectively fixing the sample. If chemical fixation is...
required, as we have seen, formalin should be the fixative of choice and samples should be carefully washed with isotonic saline before analysis.

Preparation of the cell smear is the most crucial aspect of sample preparation, and care should be taken to avoid deposition of cells in thick multilayers, which results in a long pathlength for spectroscopic measurements. Such long pathlengths will result in strong absorption of IR light and introduce artifacts into spectra caused by detector nonlinearity. The simplest method of avoiding formation of dense regions of cells is to dilute the cell suspension before preparing the smear. Alternatively, some investigators deposit monolayers of cells on the surface of the substrate by centrifugation using specialized rotors. Whichever technique is employed, this step is essential to ensure reproducible artifact-free spectra.

In some circumstances it may be of interest to study cells in an aqueous environment. In such circumstances it is important to remember to keep cells thermostated at 37 °C. Not only does this ensure that physiologically relevant information is obtained, but thermostating the sample holder when acquiring both the sample and buffer spectra allows correct compensation/subtraction of the aqueous buffer. Samples may then be analyzed in aqueous buffers containing labeled substrates or pharmacologically active substances and spectral changes induced by these substances may be monitored.\(^{16}\)

2.3.2 Preparation of Tissue Samples

Samples of tissue are prepared for IR microscopy in much the same way as for light microscopy, with some important exceptions. Samples being prepared for light microscopy are normally embedded in a liquid hydrocarbon (such as paraffin wax or products such as optimal cutting tool, or OCT), cooled to between −10 and −20 °C and sectioned using a cryotome. Typically, sections are 10–20-µm thick. However, it is important to remember to keep cells thermostated at 37 °C and sectioned in the range 0.4–0.6 absorbance units.

Having sectioned and mounted the tissue, light microscopists typically mount tissue sections on gold-coated slides and acquire reflectance–absorption spectra. However, this approach may lead to the introduction of artifacts into spectra and as adequate spectra are usually achieved with standard transmission microscopy, we suggest that this approach be avoided.

In general, once the tissue is mounted, sections should be cut to a thickness of no more than 10 µm. If the section is too thick, the intensity of resultant absorbance bands in some spectral regions (particularly the amide I region of the spectrum) will be such that problems due to detector nonlinearity will result. For most tissues, we find 7-µm sections result in acceptable spectra with adequate signal-to-noise ratios and with absorbance values in the linear range of the detector. However, sample thickness obviously depends upon the material under investigation. A good rule of thumb is to try and keep absorbance values in the range 0.4–0.6 absorbance units.

Once sectioned, light microscopists typically mount tissue on glass slides. While glass is obviously transparent to visible light, most (all wavelengths below 2500 cm\(^{-1}\)) mid-IR light is absorbed by glass. Thus, glass should be used as a substrate only if the investigator is solely interested in near-IR spectra or the CH\(_2\), CH\(_3\) and NH stretching absorptions in the mid-IR. In all other cases, the standard materials used for transmission spectroscopy (CaF\(_2\), BaF\(_2\)) should be used. Obviously, water-soluble materials such as NaCl are to be avoided. A few investigators mount tissue sections on gold-coated slides, allowing discrimination between tissue components. It is tempting to take this approach in IR microscopic studies, as it allows complete identification of tissues in the sample before spectra are acquired.\(^{17}\) However, it should be stressed strongly that under no circumstances should tissues that have been washed in xylene and/or ethanol/water be used for IR studies, because of the potential for artifacts due to delipidation and protein denaturation.

The introduction of stains into the sample may also introduce artifacts, in three possible ways. First, the stain itself may exhibit strong spectral features that confound the analysis. Second, even if the stain has no discernible IR absorptions, the interaction of the stain with species within the sample may result in spectroscopic changes. Finally, it is also possible that very weak effects not
discernible to the naked eye (either due to the stain itself or indirectly due to interactions with materials within the tissue) may bias advanced statistical analyses such as multivariate pattern recognition analysis. Such methods are capable of detecting subtle differences between tissues (see below) and thus may be affected by differential accumulation of stains within different tissue components.

The message then is simple: keep sample preparation simple and to a minimum.

3 ASSIGNMENT OF MAJOR ABSORPTIONS

Assuming the correct sampling technique has been chosen and the sample has been processed correctly, generation of large quantities of data becomes straightforward. However, interpretation of this data is not always straightforward, and relies heavily upon an understanding of the spectroscopic properties of the individual constituents of the sample. Of necessity, this assignment of IR absorptions to specific chromophores arising from individual chemical species in human tissues is largely empirical, relying upon extrapolation of IR spectra of the major components of human tissue (lipids, proteins and polynucleotides). The IR spectrum of most tissues should be closely approximated by summation of these three spectral types, weighted according to relative concentrations, and so the major spectral features characteristic of each of these building blocks and the information provided by these absorptions will be discussed. Spectra of a typical lipid, protein and a polynucleotide are shown in Figure 4 and the major peaks assigned below. It should be noted that these spectra were acquired from dry films of material to enable full-range spectra to be shown (i.e. with no interference from water). As such, the frequencies reported are those observed in the dry state, and may vary with hydration.

The spectrum of a typical phospholipid (dimyristoylphosphatidylcholine, DMPC) is shown in Figure 4(a). The dominant absorptions in this spectrum, as in the spectra of all lipids, are found in the region 2800–3000 cm\(^{-1}\) and are assigned, by analogy with IR spectra of alkanes, predominantly to the asymmetric and symmetric stretching vibrations of CH\(_3\) (2956 and 2874 cm\(^{-1}\)) and CH\(_2\) (2922 and 2852 cm\(^{-1}\)) groups of the acyl chains. As expected given the greater number of CH\(_2\) groups, the intensity of the CH\(_2\) absorptions is some 10–20 times that of the corresponding CH\(_3\) absorption. The frequency of the CH\(_2\) stretching absorptions provides a useful probe of lipid bilayer order, low frequencies being associated with a higher degree of conformational order.

In spectra of nucleic acids (Figure 4b) and proteins (Figure 4c) the intensity of absorptions in this spectral region is much reduced. No CH\(_3\) stretching absorptions are seen in spectra of polynucleotides and only weak absorptions due to the CH\(_3\) stretching vibrations of the carbohydrate residues and the C–H stretching vibrations of the bases of the nucleotides are seen. Weak features arising from the CH\(_2\) and CH\(_3\) stretching vibrations of the amino acid side chains dominate the spectrum of proteins in this region. The ratio of the relative intensities of the CH\(_2\) and CH\(_3\) stretching absorptions is much reduced compared with that seen for DMPC and reflects the almost equal proportion of CH\(_2\) and CH\(_3\) groups which occur in protein side chains.

The region between 1750 and 2800 cm\(^{-1}\) is generally free from absorptions in biological materials, the major exception being the combination band of water in wet tissue and fluids and a sharp absorption from CO\(_2\) produced by cellular metabolism which is seen in cell suspensions and biological fluids (for the purposes of this discussion we will assume that the spectrometer is adequately purged and no residual water vapor or atmospheric CO\(_2\) is present). Between 1600 and

![Figure 4 IR spectra of dry films of (a) dimyristoylphosphatidylcholine (DMPC), (b) a polynucleotide and (c) hemoglobin.](image-url)
1800 cm\(^{-1}\), absorptions attributed to C=O stretching vibrations are typically found. In phospholipids such as DMPC a strong absorption at 1736 cm\(^{-1}\) arises from the stretching vibration of the ester C=O group of the lipid. The frequency of this absorption is strongly affected by hydration (hydrogen bonding to water). In nucleic acids two major absorptions are seen which may be attributed to C=O stretching vibration of the uracil and pyrimidine bases (1717 and 1666 cm\(^{-1}\)). The absorption at 1717 cm\(^{-1}\) is a sensitive probe of base pairing in nucleic acids. In proteins the major absorption in this region is the so-called amide I band, which arises predominantly from the C=O stretching vibration of the amide C=O group. It has been repeatedly demonstrated that this absorption is conformationally sensitive and can be used to predict protein secondary structure in model studies.\(^{(13)}\)

The amide II (predominantly an N–H bending vibration coupled to C= N stretching, seen between 1500 and 1560 cm\(^{-1}\)) and the amide III (attributed to a complex vibration involving C= N stretching and N–H in plane bending, often with significant contributions from CH\(_2\) wagging vibrations, which occurs at 1220–1350 cm\(^{-1}\)) absorption bands are also used to assess protein conformation. However, as they arise from complex vibrations involving multiple functional groups they are less useful for protein structure prediction than the amide I.

The only other significant absorptions in the spectra of most proteins are attributed to side chain vibrations such as the COO\(^{-}\) asymmetric and symmetric stretching vibration of the acidic amino acids aspartate and glutamate (1580 and 1400 cm\(^{-1}\)). Collagen is a noticeable exception: in addition to a prominent series of absorptions arising from the amide III/CH\(_2\) wagging vibrations, two distinct absorptions at 1030 and 1080 cm\(^{-1}\) are seen which are attributed to C–O stretching vibrations of the carbohydrate moieties attached to this important structural glycoprotein. In fact, the series of absorptions at 1030, 1080, 1204, 1240, 1280 and 1330 cm\(^{-1}\) provide a highly characteristic fingerprint that can be used to monitor the connective tissue matrix in tissues.\(^{(19,20)}\)

In nucleic acids the region between 1000 and 1500 cm\(^{-1}\) is populated by a number of sharp but weak absorptions. The major absorptions arise from vibrational modes of the phosphate groups of the phosphodiester linkages of the polynucleotide chain and are assigned to PO\(_4\)^{2–} asymmetric (1224 cm\(^{-1}\)) and symmetric (1087 cm\(^{-1}\)) stretching vibrations.

Phospholipids exhibit similar phosphate absorptions to those shown by nucleic acids. The frequency of absorptions arising from the PO\(_4\)^{2–} groups of phospholipids can provide important information concerning headgroup hydration. In addition to phosphate absorptions, nucleic acids and phospholipids show a relatively strong absorption in this region arising from C–O–C stretching vibrations at 1050–70 cm\(^{-1}\). The only other major absorption in spectra of phospholipids arises from the CH\(_2\) scissoring vibration of the acyl chains (1469 cm\(^{-1}\)). A series of weak absorptions between 1250 and 1400 cm\(^{-1}\) are assigned to the wagging vibrations of the CH\(_2\) groups of the acyl chains.

In addition to lipids, proteins and nucleic acids, carbohydrates are present in all cells. The major absorptions from carbohydrates are found in the 1000–1200 cm\(^{-1}\) region of the spectrum and are attributed to C–O stretching vibrations. However, significant carbohydrate absorptions are only expected in those tissues with large carbohydrate stores (e.g. liver, cervix) or with a high glycoprotein (e.g. collagen) content.

Assignments of the major absorptions in biological tissues are summarized in Table 1. However, it should be stressed that these frequencies are offered as guidelines only, and that the recipe for assignment of IR absorption bands to specific chromophores involves an equal proportion of histological and spectroscopic understanding, liberally seasoned with common sense. The next section will highlight how knowledge of histology and spectroscopy can be combined successfully to aid in the interpretation of tissue spectra.

4 INTERPRETATION OF SPECTRA: ESTIMATION OF SAMPLE HISTOLOGY

Using the knowledge gained from studies of isolated biological materials, assignments of the major absorptions in IR spectra of tissues can be made. While these assignments are of course empirical, they can be made with some confidence when coupled with knowledge of potential sample histology and tissue function. Spectra of breast tissue and liver tissue will be used as illustrative examples (Figure 5).

Clear differences can be seen not only between the spectra of breast\(^{(21)}\) and liver tissue\(^{(22)}\) but also between different samples of the same tissue. These striking differences must be due to differences in composition. By attributing the major absorptions in each spectrum to specific chemical species in accordance with the assignments discussed above, the nature of these compositional differences can be suggested. Knowledge of the histology of the tissue under investigation can then be used to confirm or reject these proposed compositional differences. For example, the spectrum of breast tissue in Figure 5(a) does not exhibit the characteristic amide I absorption at around 1650 cm\(^{-1}\) typical of protein-rich tissues. Breast tissue is comprised predominantly of epithelial cells, connective tissue (predominantly type I collagen) and adipose tissue. As epithelial cells and connective tissue both contain significant quantities of protein, the lack of an amide I absorption in Figure 5(a) clearly suggests that the tissue cannot contain either epithelial cells or connective tissue. Logically the tissue must therefore consist predominantly of adipose tissue. The presence of strong absorptions arising from CH\(_2\) stretching (not shown), C=O stretching, CH\(_2\) bending and C–O–C stretching vibrations clearly point to the presence of a high proportion of lipid-like species, supporting the suggestion that this sample is composed predominantly of adipose tissue. In contrast, the breast tissue giving rise to the spectrum in Figure 5(b) is composed predominantly of protein, as indicated by the intense amide I absorption. More specifically, the series of characteristic absorptions at 1030, 1080, 1204, 1240, 1280 and 1330 cm\(^{-1}\) (highlighted on the figure) is indicative of a high collagen content, suggesting that this sample is composed predominantly of connective tissue. The third section of breast tissue (Figure 5c) exhibits a strong protein content, but no absorptions attributable to either collagen or adipose tissue. It can therefore be reliably deduced that this section of tissue is comprised predominantly of epithelial cells.

The spectrum of healthy and hypercholesteremic rabbit liver tissue differ considerably from all three spectra of breast tissue (Figure 5d and e). In particular, a strong series of absorptions is present between 1000 and 1200 cm\(^{-1}\) in healthy liver tissue. As one of the main functions of the liver is the storage of carbohydrate in the form of glycogen, it is reasonable to speculate that this series of absorptions arises from C–O stretching vibrations of glycogen present in the liver. Comparison of spectra of liver tissue with spectra of glycogen confirms this assignment. A high cholesterol diet results in significant changes in the spectrum of rabbit liver (Figure 5d). Close examination of the spectrum reveals the presence of a number of absorption bands typically found in lipid-rich tissues (e.g. a strong ester C=O
stretches absorption band, suggesting accumulation of lipid-like species in the liver. Given the fact that this rabbit was ingesting a high cholesterol diet, it seems reasonable to speculate that these lipid-like absorptions arise from deposition of cholesterol esters within the liver. Comparison with spectra of low-density lipoprotein (rich in cholesterol esters) shows a high degree of similarity, supporting this hypothesis.\(^\text{(22)}\)

Spectra of both normal and hypercholesteremic liver differ significantly from spectra of protein-rich breast samples in the region of the amide I and II absorption bands. This difference arises as a consequence of the two measurement techniques used. Breast spectra were acquired by placing thin sections of tissue between CaF\(_2\) windows. As such, the sections were still fully hydrated. On the other hand, spectra of liver tissue were recorded from an air-dried section of tissue using an IR microscope. The difference in the amide I and II profiles of protein-rich breast and liver samples therefore reflects the presence of the strong, broad O–H bending absorption at around 1640 cm\(^{-1}\) in the breast tissue, which distorts the amide I profile.

5 NONSUBJECTIVE ANALYSIS OF SPECTRA

Clearly, interpretation of spectra involves a detailed understanding of both spectroscopy and histology and entails a significant degree of subjectivity. It is possible to remove this subjectivity by the application of statistical techniques. Statistical treatments of spectroscopic data to date have usually involved multivariate pattern recognition. Multivariate pattern recognition methods fall into two basic categories: unsupervised and supervised.

Unsupervised pattern recognition methods are used to identify spectra that have similar (within some pre-determined limit) characteristics. As such, unsupervised methods are driven by gross spectral similarities and no knowledge of the nature of the sample is required. Typical examples include cluster analysis techniques such as hierarchical cluster analysis, fuzzy C-means (FCM) cluster analysis, k-means cluster analysis and ISODAT (interactive self-organized data analysis techniques) clustering. The earliest applications of such techniques to IR spectra of cells and tissues were those of Naumann et al., who applied hierarchical cluster analysis to spectra of bacteria.\(^\text{(23)}\)

These highly successful studies demonstrated that bacteria could be grouped by strain using this approach, and methods for the rapid identification of bacteria based upon IR spectra are now being developed.

In contrast, supervised pattern recognition techniques such as linear discriminant analysis (LDA) make use of the fact that the investigator often has a substantial amount of information available (either biochemical or clinical) regarding spectroscopic data.\(^\text{(24)}\) For example, the investigator may know that spectra arise from well-defined tissue types. This information may then be used to train an LDA algorithm to recognize the particular combinations of variables (peak frequencies, bandwidths, relative intensities etc.) in these spectra that are characteristic of these tissue types. The trained LDA algorithm can then be applied to unknown spectra, and the unknown spectra partitioned into one of these classes based upon the spectral patterns found.

Supervised pattern recognition techniques, including artificial neural networks and LDA, have been applied with great success to the classification of IR spectra of cells, tissues, and fluids.\(^\text{(21,25,26)}\) However, a few points should be borne in mind when applying supervised pattern recognition techniques.

Preprocessing of data is almost always a prerequisite to obtaining good classification. The simplest forms of preprocessing are normalization and derivatization. Normalization is required to ensure that classification is not based upon variations in sample thickness, while derivation may be required to remove baseline offsets which can affect classification. (It should be noted that these preprocessing steps should also be considered when employing clustering techniques).

More sophisticated preprocessing is aimed at data reduction, with the aim of removing superfluous data while simultaneously reducing computation time.\(^\text{(21,27)}\) One method of achieving this is to identify the spectral regions which contain the most diagnostic information, a process termed region selection. In practice, region selection is achieved by selecting a window of only a few data points (typically \(n = 10–12\)) within the spectrum. Beginning at one end of the spectrum, only this window of points should be used in the training and test sets. Repeat this procedure with 25 randomly generated training sets and record the average accuracy with which the test sets are classified. Next, move the window by \(n/2\) points and repeat the process. This process is repeated until the entire spectrum has been traversed. The spectral window that produced the highest classification accuracy is then determined. If this spectral window allows classification with a predetermined accuracy (say 85–90\%) then only this region of the spectrum is required for further computations. If insufficient accuracy is obtained, then all combinations of the best six to eight subregions should be used in the training set to determine the combination of these subregions that results in optimal classification accuracy.

While preprocessing is important, it is crucial to any analysis that the training set contains a sufficient number of spectra representative of the population as a
whole to allow robust training. Unfortunately, often only small data sets are available. One method of improving robustness classification with small sample sizes is to apply the leave-one-out method. This is best illustrated by an example. If we have 100 spectra in our entire database, we need to separate spectra into the training and test sets. Typically, the training set contains two-thirds of the spectra, so we have a training set containing 66 spectra. The LDA is then trained and the remaining spectra are each then classified. However, with such a small number of spectra used in the training set, the training set may not be representative of the population at large, in which case poor classification will result. An alternative approach, termed leave-one-out, makes use of the fact that each spectrum in the test set is classified independently of the other spectra in the test set. The basis of this approach is to remove one spectrum (leave-one-out) and train the LDA algorithm using the remaining 99 spectra. This trained algorithm is then applied to the single spectrum and a classification for this spectrum determined. The spectrum is then returned to the training set and a second spectrum removed. The LDA is then trained on this new training set of 99 spectra and applied to the new single test spectrum. This process is repeated, essentially using 100 discrete training sets of 99 spectra to classify the 100 spectra. This approach has been used to classify macroscopic spectra of dry films of synovial fluid as arising from either control joints or joints affected by one of three forms of arthritis with an accuracy of greater than 95%.\(^9\)

Another effective method for developing a robust training set is known as bootstrapping.\(^21\) Using this approach the data are split randomly into training and

![Figure 6](image_url) Photomicrographs of skin biopsies showing regions of tissue used to produce spectra of “pure” tissue components. Derivative spectra from each region are shown.
test sets with two-thirds of the spectra in the training set. The classifier is then trained, and a new training set of 66 spectra is randomly selected. This process is repeated, typically 250 times, and the average classifier from these 250 iterations computed. This average classifier is then applied to all 100 spectra.

Both the bootstrapping and the leave-one-out methods enhance the robustness of LDA by reducing the risk of “overtraining”. With a test set that is unrepresentative of the population at large one runs the risk of reaching a suboptimal solution, that is a local minimum rather than a global minimum. The use of large training sets which adequately represent the population at large or the average classifier resulting from multiple training sets reduces the likelihood of this occurring.

The robustness of spectral analysis by supervised classification techniques is also affected by the requirement for assignment of spectra to a particular class of tissue. Uncertainty about the histology of the sample can result in uncertainty or “fuzziness” of classification. For example, in a recent study of breast tissue a novel classification strategy was required to classify spectra of breast tumor by grade, as a traditional approach to LDA proved to be unsatisfactory. To a large extent, this difficulty arose because spectra were obtained by transmission methods. As discussed above, such spectra represent an average of all tissues present in the sample, which in this instance may be normal epithelial cells, epithelial cells exhibiting varying different degrees of malignancy, adipose tissue and connective tissue. Obviously such a complex composition makes assignment of macroscopic spectra to a particular class difficult.

This problem may be alleviated by the acquisition of spectra with the use of an IR microscope. The ability to generate highly accurate classifiers using spectra of essentially pure tissue components has been demonstrated in studies of skin biopsies. The ability to acquire spectra from 30 × 30-µm regions of tissue ensured that spectra of tumor, epidermis, dermis, stroma and hair follicles could be obtained without contamination by the other tissues (Figure 6). Notable differences may be seen between the derivative spectra of the five tissue components. For example, spectra from the dermis and the stroma running throughout the tumor body exhibit the characteristic signature of collagen. In contrast, spectra obtained from the follicle sheath and sebaceous glands exhibit strong lipid absorptions arising from sebum, a complex mixture of lipids, acylglycerides, waxes, squalene, cholesterol and cholesterol esters of unknown function. Finally, the epidermis and tumor could be differentiated by a reduced protein : nucleic acid ratio in regions of tumor.

It can readily be seen that IR microscopic examination of skin allows individual tissue components to be identified. Acquisition of spectra from a number of skin biopsies in this manner allowed a large representative database of spectra of the pure tissue components to be produced. Application of LDA to this data set allowed classification of spectra of each of the tissue components with extremely high accuracy (98%).

Clearly the application of pattern recognition techniques to IR spectra of cells and tissues allows non-subjective classification of spectra with an impressive degree of accuracy. However, it should be stressed that no classification strategy can account for poor data, and it is vital that care be taken to ensure that all spectra are characterized by linear detector responses, high signal-to-noise ratios and good water vapor compensation.

6 ANALYSIS OF MICROSCOPIC MAPS

In standard transmission methods, a single spectrum is obtained which describes the gross spectroscopic characteristics of the sample. An estimate of gross sample histology can be obtained relatively easily by analyzing the spectrum using the approach described above. With the acquisition of spectra from single points by IR microscopy, spectra of pure tissue components may be obtained and data correlated with sample histology, allowing characterization of tissues with much higher precision in a relatively straightforward manner. However, with IR microscopic mapping this single spectrum is replaced by many thousands of spectra, and data analysis and presentation present unique challenges. While the interpretation of individual spectra from a mapping experiment can be achieved as described above, this approach is obviously impractical when analyzing a map containing 10,000 spectra. A number of more efficient methods for analysis of spectroscopic maps have recently been developed, many of which are borrowed from, or have parallels in, image processing.

6.1 Functional Group Mapping

The most straightforward and most common method of analyzing and presenting data from IR microscopic mapping experiments is so-called functional group mapping. In functional group mapping, parameters obtained from a functional group of interest are plotted as a function of position within the map. The parameters that may be plotted depend upon the information sought. Examples of parameters that may be plotted include the frequency of an absorption maximum, the peak intensity of an absorption band, the integrated intensity of an absorption band and the ratio of peak or integrated intensities.
6.1.1 Intensity Maps

As the intensity of a functional group is directly proportional to the concentration of the material giving rise to the absorption, plotting the intensity (either peak intensity of integrated intensity) of a functional group at each pixel within a map provides a simple method for assessing the distribution of the material throughout the sample. A number of approaches are available for calculation of peak intensities, and care must be taken to choose the correct method and avoid the introduction of artifacts.

Calculation of intensity values is most straightforward if performed using the original absorption spectra, although baseline fluctuations may be problematic. For example, spectra of tissues often show a considerable baseline slope and offset due to scattering effects. In a map containing thousands of spectra, this offset and slope are likely to vary considerably. Simply calculating the peak height above a zero baseline will therefore lead to artifactual changes in intensity that are related to changes in this slope and offset rather than absorption intensity. It is therefore important that investigators include some type of baseline compensation in intensity calculations to avoid introduction of erroneous variations in intensity. The position is similar when considering integrated intensities, the correct calculation being the area enclosed by the spectrum and this baseline.

Unfortunately, in many instances it is not feasible to analyze absorption spectra because of overlap of the absorption band of interest with other absorption bands. Calculation of second derivative spectra may result in sufficient separation of absorption bands to allow calculations on such highly overlapped absorption bands and has the additional advantage that baseline variations are removed. However, calculations on derivative spectra require considerable care, for a number of reasons. First, second derivative spectra exhibit negative peaks. The presence of negative values results in presentational problems, as the functional group maps will be inverted. Second, most derivative peaks have both positive and negative contributions, which may have a significant impact upon the calculation of both peak and integrated intensities. For example, reading of the value at the minimum of an absorption band in derivative spectra significantly underestimates the height of the derivative peak, as the contribution of the positive components of the peak are ignored. Finally, broad, weak absorption bands may produce derivative peaks that have intensity values that vary around zero, which complicates interpretation.

Inversion of spectra and the application of an offset correction to ensure that all calculated values are positive remove these problems. Following derivation, inversion and offset correction, calculation of reliable peak or integrated intensities is possible. However, again a baseline should be included to define the absorption band of interest, and either the height above this baseline or the area bounded by the baseline and the absorption band calculated.

With adequate precautions, the distribution of materials within tissues can now be monitored. Absorptions of particular interest are those arising from lipid (e.g. the symmetric and asymmetric CH\textsubscript{2} stretching and ester C=O stretching absorption bands), DNA (C=O stretching absorption band, phosphate stretching absorption bands), protein (amide I absorption) and collagen (amide II absorption at 1204 cm\textsuperscript{-1}). Plotting the intensity of these absorption bands as a function of position allows the distribution of lipids, protein and DNA to be assessed, which provides an overview of the gross biochemical characteristics of tissues.

This utility of intensity-based functional group mapping for characterizing tissue is illustrated in Figure 7, which shows functional group maps obtained from a section of skin containing a basal cell carcinoma. To aid interpretation of the functional group maps, skin morphology will be briefly discussed. The outermost layer of the skin is the epidermis (see Figure 7a). The epidermis consists of densely packed keratinized epithelial cells that grow in layers, the deepest cell layer resting on the basement membrane that separates the epidermis and dermis. The dermis or connective tissue layer is significantly thicker than the epidermis and is largely acellular, consisting mainly of a connective tissue matrix comprised of collagen fibrils. It supports sebaceous glands and hair follicles, which are surrounded by a layer of epithelial cells called the follicle sheath. These anatomical structures are highlighted in Figure 7(a). Two regions in which the tissue has become folded during deposition on to the window are also highlighted, as these regions of tissue are potential sources of artifacts.

The amide I intensity, which may be used to monitor protein distribution, is plotted in Figure 7(b) as a function of position within the map. The highest concentration of protein is seen in the regions of folded tissue. This is expected, as the pathlength in this region of the tissue is obviously greater than in the surrounding tissue. Clearly this is artifactual and does not provide useful information relating to the composition of the tissue in these regions. Such regions of the tissue should be ignored when interpreting data, and whenever possible tissue sections containing folds should not be analyzed. In the remaining tissue, the highest protein concentration is seen in the outer layers of the skin, corresponding to the epidermis. The protein concentration is generally reduced in the dermis and is lowest in the region of the tissue containing the tumor. However, small islands of high protein concentration can be seen, and these islands of protein clearly correspond to hair follicles. This
Figure 7 (a) Photomicrograph of a skin biopsy. Functional group maps showing distribution of (b) protein (amide I peak height), (c) collagen (peak height at 1204 cm\(^{-1}\)), (d) lipids (peak height at 1740 cm\(^{-1}\)) and (e) nucleic acids (peak height at 1718 cm\(^{-1}\)).
distribution results from the differences in composition of the three tissues. The epidermis consists of tightly packed cells, many of which have significant deposits of keratin, which results in a high protein content of this tissue. Hair follicles are surrounded by a layer of cells that have the same origin as the epidermal cells, and thus exhibit the same high protein content. It is interesting to note however the low protein content at the center of the hair follicle, which arises because hairs are hollow.

The dermis is largely acellular and consists predominantly of collagen fibers interspersed throughout a glycosaminoglycan ground substance. The protein content is thus reduced compared to the epidermis. The region of the tumor exhibits the lowest protein content. This is most likely to be a consequence of nuclear enlargement which is seen in many tumor cells and which reduces the amount of cytoplasm, and so protein, inside the tumor cells.

The distribution of intensity at 1204 cm$^{-1}$, which corresponds to collagen distribution, is notably different from the distribution of the amide I intensity (Figure 7c). No intensity is seen at 1204 cm$^{-1}$ in the region of the epidermis, but strong contributions are seen in the region of the basement membrane, hair follicles and sebaceous glands. Such a distribution of intensity is expected given that the basement membrane is composed predominantly of collagen, while hair follicles and sebaceous glands are both surrounded by a protective collagen sheath. A more diffuse distribution of collagen, corresponding to the collagen fibers interspersed throughout the ground substance, is apparent in the dermis.

As seen when monitoring protein distribution, artificially high lipid concentrations are seen in regions of folded tissue (Figure 7d). Again, these regions of tissue should be ignored. Strong contributions from lipid can clearly be seen in the region of hair follicles and sebaceous glands, but little lipid-like material is seen in other regions of the sample. The appearance of lipid-like material in sebaceous glands and hair follicles is the result of the presence of sebum. Interestingly, it can be seen that the low concentration of protein seen at the center of hair follicles corresponds to peaks in sebum content, suggesting that at the level at which the hair follicles have been sectioned the center contains a plug of sebum.

Finally, the distribution of DNA, as indicated by the distribution of intensity of the DNA absorption at 1718 cm$^{-1}$, is markedly different from the distribution of other materials, with the highest intensity appearing in the region of tumor (Figure 7e).

From this brief discussion, it should be apparent that discrete tissue types within a sample can be identified based upon the distribution of the major biochemical species present.

### 6.1.2 Frequency Maps

While plotting intensity information provides information concerning the amount of materials at each position within the map, plotting the frequency of absorption maxima as a function of position provides information relating to structural properties. For example, plotting the frequency of the amide I absorption maximum (or the center of gravity of the amide I absorption band) provides information relating to variations in protein structure throughout the tissue. Such information may be useful in the characterization of proteinaceous deposits associated with pathological conditions. A recent study illustrated the effectiveness of this approach in tissues affected by AD.$^{28}$

AD is characterized by progressive degeneration of the gray matter of the central nervous system. It is believed that deposition and self-association (aggregation) of a peptide known as βA4 amyloid lead to the formation of so-called neuritic plaques. Neuritic plaque formation is followed by neuronal death producing severe cortical atrophy and loss of language skills, memory and intellectual function and disorientation. The accumulation of βA4 is one of the major pathological hallmarks of AD, and the structure of the peptide in situ is of considerable interest.

To locate deposits of βA4 in situ, intensity-based functional group mapping may be used. Deposition of the peptide should lead to a significant increase in amide I intensity in the region of the neuritic plaque. This is illustrated in the amide I functional group map produced from maps of the tissue shown in the photomicrograph in Figure 8(a), which contains an amorphous deposit which may be a neuritic plaque. Analysis of the amide I functional group map shows that there is indeed a dramatic increase in the integrated intensity of the amide I band in the center of the area mapped, corresponding exactly to the amorphous deposit of interest (Figure 8b). This observation implies that the amorphous deposit is proteinaceous in composition. However, it does not allow any conclusions concerning the structure of the protein in the deposit to be drawn. To obtain this information, a plot of the center of gravity of the amide I absorption as a function of position is required.

Frequency-based functional group maps are usually presented as two-dimensional contour plots. The contour plots are color coded according to the center of gravity of the amide I. In the representation shown in Figure 8(c), orange/red coloration corresponds to an amide I center of gravity at 1650–56 cm$^{-1}$ while blue coloration corresponds to an amide I center of gravity at 1630 cm$^{-1}$. As the frequency of the amide I is indicative of protein structure, regions of the tissue containing proteins with different secondary structures are colored differently. Thus, regions of the tissue containing aggregated proteins are shown
INFRARED SPECTROSCOPY, EX VIVO TISSUE ANALYSIS BY

Figure 8 Photomicrograph of Alzheimer’s tissue showing the region mapped (a) and intensity-based (b) and frequency-based (c) functional group maps derived from the amide I absorption.

in blue, while those containing predominantly unordered and/or helical proteins are shown in orange/red.

The area corresponding to the proteinaceous deposit can clearly be seen to exhibit a low amide I frequency (1630 cm\(^{-1}\)) indicative of aggregated protein. This strongly suggests that the protein deposit identified by intensity-based functional group mapping is a neuritic plaque. Staining of the tissue with Congo red, a stain that specifically colors amyloid deposits pink/red, revealed that the mass was indeed a neuritic plaque, confirming the spectroscopic assessment (Figure 8a).

Frequency-based functional group mapping may also be used to monitor variations in more subtle structural parameters such as membrane fluidity. The frequency of the absorptions attributed to CH\(_2\) symmetric and asymmetric stretching vibrations of lipids are sensitive to the degree of conformational order within membranes. Increased membrane disorder (i.e. a more fluid environment) is associated with an increase in the frequency of the CH\(_2\) stretching absorption bands. Thus, a plot of the frequency of the CH\(_2\) stretching absorption band frequency may be used to probe membrane dynamics in tissue sections and to assess variations in membrane dynamics. Although such studies have been few to date, potential applications include investigation of neurological disorders, particularly those involving lipid-rich white matter such as multiple sclerosis.

While frequency-based functional group mapping is potentially a powerful method for assessing structural properties of tissues, care should be taken in interpreting results. Particular care should be taken when the chromophore of interest arises from more than one biochemical species. For example, the CH\(_2\) stretching absorption bands in tissues may arise predominantly from lipids but often contain significant contributions from proteins. As the frequency of CH\(_2\) stretching absorption bands differs in lipids and proteins, the frequency of this composite absorption is determined by the frequencies of the CH\(_2\) stretching absorption bands of the lipid and protein components and the relative proportions of lipid and protein. A change in the frequency of this composite absorption band may therefore result from a change in the frequency of the lipid CH\(_2\) stretching absorption bands, a change in the frequency of the protein CH\(_2\) stretching absorption band or a change in the relative amounts of lipid and protein.

To distinguish between these three possibilities requires other functional group maps to be examined. For example, examination of the amide I frequency-based functional group map will allow the effect of variations in protein structure to be assessed, while examination of the amide I and lipid C=O intensity-based functional group maps allow the role of variations in lipid and protein content to be determined. If these parameters remain constant across the area of the map of interest then a change in membrane fluidity may then be inferred.

6.1.3 Ratio Maps

While intensity- and frequency-based functional group maps provide much information, this information typically relates only to a single chromophore. From the brief discussion above it can be seen that there are often instances when the ratio of materials (for example lipid and protein) within tissue is of interest. In such cases, functional group maps that represent the ratio of a parameter measured for two distinct chromophores may be of use. For example, a ratio map showing the variation in the lipid:protein ratio across a tissue section can be calculated in a number of ways. The most obvious methods involve measuring the intensity of the amide A, amide I, or amide II absorption band from proteins and
the intensity of the CH$_2$ asymmetric or symmetric stretching or CH$_3$ bending absorption band of lipids. The ratio of the intensity of any of the lipid absorption bands to any of the protein absorption bands will provide an indication of the variation of the lipid:protein ratio across the tissue.

Two important, if obvious, factors should be stressed. First, the lipid:protein ratio obtained will depend upon the chromophores used. Second, the lipid:protein ratio obtained will be different if the investigator uses absorption or derivative spectra, even if the same chromophores are used to calculate the ratio, as relative intensities are not retained in derivative spectra. Obviously then this methodology shows only trends in the lipid:protein ratio across the tissue, and cannot be used to calculate absolute values. However, as interest is usually in changes in ratios within the tissue, this does not usually represent a problem.

A second method of estimating changes in the lipid:protein ratio across the surface of a tissue section involves calculating the ratio of the CH$_2$ and CH$_3$ stretching absorptions. Both lipids and proteins give rise to CH$_2$ and CH$_3$ stretching absorptions. However, the ratio of the intensity of the CH$_2$ and CH$_3$ absorption bands is significantly different in lipids and proteins. Lipids typically contain 14–18 CH$_2$ groups and only one CH$_3$ group per acyl chain, while proteins contain almost equal proportions of CH$_2$ and CH$_3$ groups in their side chains. Thus, the CH$_2$:CH$_3$ intensity ratio for lipid-rich and protein-rich tissues differs substantially. Plotting the CH$_2$:CH$_3$ intensity ratio as a function of position therefore provides an alternative method of monitoring variations in the lipid:protein ratio throughout tissues.

6.1.4 Gray Scale Imaging

While visualization of the distribution of tissue components by functional group mapping is a powerful method of analysis, it requires a degree of familiarity to generate maps with the correct orientation or numbers of contours to portray information usefully. This is particularly so for two-dimensional contour plots. This can be avoided by converting the maps to gray scale images, in which each pixel is assigned a value between 0 (white, no absorption) and 255 (black, total absorption) depending upon the intensity of the absorption band under investigation.$^{129}$ Gray scale functional group maps calculated from absorption bands at 2924, 1650, 1204 cm$^{-1}$ and the ratio at 1240/1204 cm$^{-1}$ for the tissue section shown in Figure 2 are shown in Figure 9. The CH$_2$ stretching absorption band gray scale map (2924 cm$^{-1}$, Figure 9a) indicates a high lipid content (areas shaded black) around hair follicles and in sebaceous glands. Additionally, there is a high lipid CH$_2$ content in the epidermis, probably owing to membrane phospholipids in the keratinocytes of this skin layer. The dermis and stroma have low lipid content indicating the relatively low amount of cellular material in these skin areas.

Protein deposition within the section closely follows lipid deposition (Figure 9b), with the highest protein content seen in the epidermis and hair follicles and the lowest protein content seen in the tumor. As discussed above this low protein content arises from nuclear enlargement, decreasing the volume of cytoplasm within tumor cells.

Collagen (1204 cm$^{-1}$) distribution throughout the section (Figure 9c) is clearly different from total protein distribution. Collagen content is very high in the dermis of the skin, especially in dermis close to the tumor area. As expected, the tumor region contains little if any collagen.

Monitoring nucleic acid distribution in tissue sections can be difficult. In Figure 7 the intensity of the DNA absorption at 1717 cm$^{-1}$ was used as a marker for DNA content. However, in many tissues this weak absorption is difficult to detect. In such tissues the only option is to analyse the PO$_4^-$ stretching absorption bands at 1240 and 1080 cm$^{-1}$. However, each of these absorption bands contains contributions from phosphate groups of phospholipids and the amide III absorption band of collagen. Analyzing absorptions at 1240 and 1080 cm$^{-1}$ is therefore inadvisable as a method of monitoring nucleic acid distribution.

We have found that the most reliable method for tracking nucleic acid content in the absence of a clear absorption band at 1717 cm$^{-1}$ is to monitor the ratio of absorbance at 1240/1204 cm$^{-1}$. Collagen exhibits absorption bands at both frequencies, while nucleic acids exhibit an absorption band only at 1240 cm$^{-1}$. Thus, this ratio will provide a useful indication of the relative proportions of nucleic acids and collagen. A high ratio indicates a high nucleic acid content, a lower ratio indicates significant collagen contributions. For practical purposes, the contributions from lipid phosphate groups can be ignored in tissues without a significant adipose tissue component. This can be verified by examination of the ester C=O stretching band at 1740 cm$^{-1}$. The lipid phosphate and ester C=O absorptions exhibit approximately equal intensity in isolated materials. As the lipid C=O absorption is typically weak in most tissues, then it can be assumed that the lipid phosphate groups contribute minimally to the absorption at 1240 cm$^{-1}$ in most tissues.

The distribution of nucleic acids (1240/1204 cm$^{-1}$) in the tissue section is shown in Figure 9(d). The epidermis, follicle sheath and tumor area all have a high content of nucleic acids. The dermis and stroma exhibit the lowest
nucleic acid content. Interestingly, this presentation allows the most fine structure to be visualized within the tumor, clearly allowing detection of the stroma running throughout the body of the tumor.

It is apparent that functional group mapping, either in the form of two-dimensional contour plots or three-dimensional intensity plots or gray scale images, readily identifies the major tissue types in skin due to their widely different chemical compositions (i.e. collagen in dermis, lipid in adipose tissue, etc.). However, such representations of data allow only the distribution of one or two (in the case of ratio maps) components to be assessed in a given map. It would be of more practical use if many components could be simultaneously displayed in one map. This is achieved with a technique known as digital staining.

6.1.5 Digital Staining

As its name implies, digital staining mimics the process of staining tissues, allowing discrimination of tissue components based upon color. In digital staining, 8-bit gray scale images showing the distribution of three tissue components are converted to 8-bit red, green and blue scale images. These 8-bit images are then combined to produce 16- or 24-bit images. By superimposing the chemical information contained in the separate functional group maps, digital staining provides a means of representing relative proportions of chemical species visually.

Figure 9(e) shows the digitally stained map obtained by combining the functional group maps for protein and nucleic acids shown in Figure 9(b) and (d). The nucleic acid gray scale map was converted to a green scale map while the protein gray scale map was converted to red.
subjectivity reduces the usefulness of the technique in a clinical setting. To remove or reduce this subjectivity a number of unsupervised multivariate pattern recognition/classification techniques, particularly cluster analysis techniques, have been applied to spectroscopic maps.

6.2 Nonsubjective Analysis of Microscopic Maps

Functional group mapping, either as three-dimensional intensity plots, two-dimensional contour plots, gray scale images or digitally stained images, is clearly a powerful analytical tool. However, in order to understand the significance of such plots this method requires absorption bands to be assigned to particular functional groups, which may not only be difficult but also highly subjective, even for the trained spectroscopist. This inherent subjectivity reduces the usefulness of the technique in

6.2.1 Unsupervised Methods: Cluster Analysis

Unsupervised pattern recognition techniques classify data based upon gross spectral features. Classification is therefore based upon inherent properties of spectra, and no knowledge of the nature of the sample is required. For example, cluster analysis techniques may be used to group spectra based upon some measure of similarity. This will be illustrated by a description of a technique known as ISODAT clustering, one of the most straightforward methods of cluster analysis. ISODAT clustering requires an estimate of the number of clusters expected together with the minimum size of each of the clusters (i.e. the minimum number of spectra in each cluster). In addition, an estimate of the maximum standard deviation that is acceptable within a cluster before the cluster is split into two smaller clusters and the minimum difference between the means of different clusters which is acceptable before the clusters are merged are required.

ISODAT clustering partitions the data set randomly into the estimated number of clusters, n. The mean and standard deviation are then calculated for each cluster. The means of all of the clusters are then compared. If the difference between the means of any two clusters is less than the threshold value set then it may be deemed that spectra within these two clusters exhibit a high degree of similarity and the clusters are merged. If on the other hand the standard deviation of any cluster is above the standard deviation threshold set then it may be inferred that spectra in this cluster show a high degree of dissimilarity. This cluster is then split to reduce the standard deviation of the two new clusters below the threshold value. The cluster mean and standard deviation thresholds therefore determine the sensitivity of the analysis. This process is iterated to produce the optimal number of clusters for the input parameters.

ISODAT cluster analysis was applied to a section of hypercholesteremic rabbit liver. The area outlined in Figure 10(a) was mapped, spectra were truncated to the region 3100–3690 cm⁻¹ (N–H stretching vibrations, to decrease computation time) and the maximum allowed standard deviation set to 12%. Each shaded block in Figure 10(b) corresponds to spectra acquired from a 40 x 40-μm pixel of tissue, with steps of 51 and 48μm in the x and y directions. Pixels of the same shade belong to the same cluster. Clearly with the parameters used in this analysis five distinct clusters can be seen, implying the presence of five discrete tissue types with different
Figures 10 Photomicrograph of hypercholesteremic liver tissue showing the area mapped (a, white box) and the results of ISODAT cluster analysis of spectra (b). Pixels shaded the same color belong to the same cluster.

populations of N–H groups. It can be seen that two of these populations are found almost exclusively in the region of the tissue corresponding to the yellow streak caused by bilirubin deposition in the tissue.

FCM cluster analysis uses similar principles, partitioning spectra such that the differences in the intracluster spectral responses are minimized, while simultaneously maximizing the intercluster differences between spectral responses. Application of FCM cluster analysis to IR microspectroscopic maps of skin tissue is illustrated in Figure 11. Five discrete clusters of spectra were identified. Comparison of the cluster map (Figure 11b) with histological data (Figure 11a) reveals that the clusters correspond to distinct histological types. Pixels colored turquoise correspond to adipose tissue and sebaceous glands in the histological section. Spectra in this cluster exhibited the highest lipid intensities, the highest ester C=O stretching vibration and the lowest amide I and II intensities. Pixels shown in blue are found almost exclusively in the dermis. Spectra in this cluster exhibited the series of absorptions assigned to collagen vibrations. The clustering routine did not differentiate between the two layers of the dermis. Pixels shown in yellow are interspersed throughout the body of the tumor. Spectra in this cluster exhibited weak collagen absorptions, and are most likely to arise from regions of stroma within the tumor. This stromal component is not the same as that seen in the dermis, as it occurs in a separate cluster. This may be due to spectral contributions from malignant epithelial cells in the stroma interspersed throughout the tumor. Alternatively, it may indicate a difference in the chemistry of the stroma in the two locations (i.e. matrix modifications induced by the tumor cells). Green pixels correspond to the majority of tumor
cells (nodular-type basal cell carcinoma). Spectra in this cluster exhibited weak lipid absorptions and minimal collagen absorptions. An additional cluster (shown in red) is interspersed throughout the tumor. Spectra in this cluster were similar to those in the larger, green cluster, but correspond histologically to infiltrative tumor regions.

Clearly, cluster analysis techniques can be used to distinguish between tissue compartments having similar spectral, and so biochemical, features. However, as discussed above, cluster analysis techniques group spectra based solely upon gross spectral similarities. Clusters of spectra that exhibit only small spectral differences may therefore be grouped together. In addition, the biochemical/histological basis for the appearance of these groupings must still be determined by visual assessment and interpretation of spectra from each cluster. Techniques that are better able to separate tissue compartments showing subtle spectral differences and which require no visual interpretation to allow attribution to specific histological groups are therefore required. Supervised pattern recognition methods are potentially better suited to the development of such data analysis methods.

6.2.2 Supervised Methods: Linear Discriminant Analysis

LDA has been very successful when applied to single spectra obtained from multiple tissue samples. An obvious extension is to use LDA to develop "search" methods that can be used to locate individual tissue components within a spectroscopic map of tumor-bearing skin.

As discussed above, we have used spectra acquired from pure components of skin biopsies to train a linear discriminant algorithm to recognize spectra of tumor, epidermis, dermis and follicle sheath. This analysis was extended to allow LDA to be performed on the skin biopsy discussed in section 6.1. Briefly, 914 spectra acquired from a range of skin biopsies were used as the training set for an LDA. To reduce computation time the combination of spectral subregions that allowed the most efficient discrimination between spectral classes were identified. The 10 subregions so identified were then used to train the LDA algorithm to partition spectra into the five classes (epidermis, dermis, follicle sheath/sebaceous glands, stroma or tumor). The trained LDA was then applied to the spectroscopic map. The implementation of LDA used in this study returned a membership value for each spectrum in the spectroscopic map. For each...
Infrared spectroscopy, ex vivo tissue analysis by

Spectrum, a value ranging between 0 (not belonging) and 1 (belonging) is returned which indicates membership of each class, with the sum of values for all classes being unity. The values returned therefore provide an indication of the likelihood of the spectrum at a particular pixel belonging to each of the five classes. Thus, for a spectrum that arises from tumor, the ideal result would be a returned value of 1 for the tumor class and 0 for all other classes.

To simplify data interpretation, a visual representation of the results of the LDA can be produced by plotting the membership values of spectra at each pixel for each of the five classes, with the data displayed as a gray scale image. In this representation, a likelihood of zero for a spectrum belonging to a particular class results in pixels being shaded black, while a likelihood of one results in pixels being shaded white. Figure 12 shows the gray scale images of the membership values for tumor, dermis and stroma. All membership likelihood maps in Figure 12 correspond well with histological detail. For example in Figure 12(a) areas shaded white (high likelihood of membership of the tumor class) correspond exactly with the tumor area on the histological section (cf. Figure 2). Similarly, the light regions in the membership maps shown in Figure 12(b) and (c) correspond to stroma and dermis regions in the stained tissue section.

Figure 12 Gray scale maps indicating the likelihood of tissue belonging to (a) tumor, (b) dermis or (c) stroma as predicted by LDA. Digital staining was then applied to produce color-coded membership likelihood maps for (d) tumor (red), dermis (blue) and epidermis (green) and (e) tumor (red), follicle sheath (green) and epidermis (blue). See text for more detail.
Considerable fine structure is seen for some membership likelihood maps. For example, the stroma membership likelihood maps clearly show regions of stroma running through the body of the tumor. While the likelihood of these pixels containing stroma is high, it is significantly below 1 and the stromal fibers running through the tumor appear as gray pixels. Presumably this results from the fact that even with relatively small aperture sizes, spectra from these pixels contain contributions from both the fibrous stroma running through the tumor and also from tumor cells, reducing the stroma membership likelihood for these pixels. Interestingly, stromal regions are also identified within the dermis (bright areas in Figure 12c). The most likely origin of this “stromal signature” is the collagen sheath that surrounds hair follicles and sebaceous glands. This suggestion is supported by the concordance between the position of these bright regions and follicle and sebaceous glands within the dermis in Figure 2.

To display the likelihood of membership of more than one class simultaneously, the digital staining approach may be used. In this case, three membership likelihood gray scale maps are converted to red, green and blue scale maps and the images combined as described above. Superimposing three maps such that the color displayed for each pixel is the combined RGB value from the three individual maps then creates a composite image which provides information about the likelihood of membership of a pixel in three classes simultaneously. In essence, this produces a color-coded membership likelihood map.

Examples of color-coded membership likelihood maps produced by digital staining of the LDA results are illustrated in Figure 12(d) and (e). Figure 12(d) combines the likelihood maps for tumor (red), epidermis (green) and dermis (blue). Thus, a high likelihood of a pixel falling into the tumor class results in the appearance of a red pixel, in the epidermis class a green pixel and in the dermis class a blue pixel. The striking feature of the digitally stained LDA results is the excellent discrimination between the three classes, and how closely the classes correspond to histological tissue compartments. There can be no question that spectra of basal cell carcinoma tumor cells are distinct from any of the other tissue components in this skin section (green and blue). The demarcation between tumor and dermis can clearly be seen, providing excellent tumor marginalization.

Figure 12(e) combines the likelihood maps for tumor (red), epidermis (blue) and follicle sheath/sebaceous glands (green). Again, excellent discrimination is seen between the three tissue types. This is particularly gratifying given the fact that the epidermis, tumor and follicle sheath share a common cellular origin (epidermal cells). Despite this similarity in origin a clear differentiation between these three tissue components is seen, highlighting the power of this analytical approach. Interestingly, there is currently some debate as to the origin of basal cell carcinoma. While many investigators feel that the tumors are epidermal in origin, others feel that the follicle sheath is a more likely point of origin. Whatever the origin of the tumor, it is clearly a distinct spectroscopic entity.\(^{33}\)

**7 SUMMARY**

Long before the instrumental advances that revolutionized IR spectroscopy, Sutherland and Thompson commented that “the infrared spectrum of a chemical compound is probably the most characteristic property of that compound”.\(^{34}\) Half a century later technical developments have firmly established IR spectroscopy as the most widely applicable analytical tool. This highly versatile technique has now found yet another new application: ex vivo characterization of tissues, cells and biofluids. While this application is new, the general principles that guide design and implementation of all good spectroscopic experiments hold true. Obtaining adequate spectra requires the correct choice of sampling technique, appropriate sample preparation and common sense. With these precautions observed, a wealth of information can be extracted from spectra. However, to make use of this information a unique combination of spectroscopic and histological knowledge is required.

The complexity of the information obtained from spectroscopic studies of tissues, particularly those involving IR microscopy, provides a daunting challenge to the IR spectroscopist, but one that can be overcome. Statistical methods play an important role in analysis of large IR spectroscopic data sets, although this field is still in its infancy. Equally important, effective presentation of the large volume of data which is routinely generated is crucial, and methods such as gray scale imaging and digital staining described here will be important factors in determining the degree to which IR spectroscopy becomes generally accepted as a tool for tissue characterization.

In summary, IR spectroscopy has become a powerful tool for the analysis of tissues, cells and biofluids. With a few simple precautions and a multidisciplinary approach, information relating to normal biochemistry and pathological processes within tissues can be reliably obtained. This information may be used to further the understanding of disease processes or may be used to develop novel methods for diagnosis, staging, prognosis and therapeutic monitoring.

Angiography generally refers to any imaging method that can visualize blood vessels. Magnetic resonance angiography (MRA) is a class of magnetic resonance (MR) imaging techniques that create blood vessel images. During the past decade, there has been a tremendous amount of development and refinement in MRA techniques, making MRA a powerful tool in the diagnosis of cardiovascular disease. In most of the cases, MRA techniques are applied noninvasively, without the use of ionizing radiation. The inherent advantages of MR imaging (noninvasive, flow sensitive, high soft tissue contrast, and flexible imaging approaches) make it ideally suited to the study of the vasculature in almost any part of the human body. MRA presents a wide spectrum of techniques for the study of flowing blood: different methods for high spatial resolution, high temporal resolution, velocity sensitization, flow quantification, and visualizing pulsatility. This article addresses the basic principles of MRA and describes its applications.

1 INTRODUCTION

Blood flow phenomena and the basics of flow measurement with MR were recognized long before the invention of MR imaging. \(^1,2\) Singer proposed to determine blood flow rates using MR relaxation time measurements in mice. However, flow phenomena in actual MR images of humans were not reported until 1977, by Hinshaw. \(^3\) He observed that in single-slice transverse images of the wrist, vessels appeared as high intensity structures. Developments in medical applications of MR imaging have caused renewed interest in flow for two reasons: first, flow effects are a significant source of image artifacts in many clinical applications. \(^4,5\) Second, and perhaps most importantly, flow imaging techniques can be devised which exploit these effects, showing clear pictures of blood vessels and allowing for the study of blood flow phenomena (Figure 1). Since 1985, when MRA was first shown to be clinically feasible, \(^6\) the imaging techniques and hardware used for MRA have greatly improved. As little as fifteen years ago, MRA was rarely utilized clinically, whereas it now has become commonplace in the standard care of patients. \(^7\)–\(^10\)
2.1 Time-of-flight Phenomenon

It is well known that the excitation and detection of a MR signal are not simultaneous. Bulk motion of flow during image acquisition can give rise to TOF effects. TOF effects are changes in the MR signal due to spins flowing into, or out of, an imaging volume during the application of an imaging sequence. For example, if a vessel containing flowing blood passes through a slab of tissue being imaged, the bolus of blood which experiences the 90° radiofrequency (RF) pulse may be outside the slab when the refocusing 180° RF pulse occurs. In this case, the magnetization of the blood is not refocused, and no signal is observed within the vessel. This is usually referred to as “flow void”.[11] Based on this phenomenon and other flow signal suppression schemes, one class of MRA techniques, named “black blood MRA”, have developed.[12] However, another TOF effect, referred to as “inflow enhancement” or “bright blood MRA”, is used more widely in clinical application.

The cause of inflow enhancement is physical displacement of the spins between successive RF excitation. This enhancement is especially true for gradient echo based imaging sequences, since a single RF pulse (as opposed to a 90°–180° train in spin echo sequence) is applied for each data acquisition. The basic idea is illustrated in Figure 2. Let us assume the blood flow to be perpendicular to the imaging slice. For an image sequence, repetition time (TR) is shorter with respect to the stationary tissue’s longitudinal relaxation time (T1) within the slice, where the magnetization becomes saturated by the RF excitations and gives low signal intensities. Blood flow in the vessel moves spins from outside the slice, which are in an unsaturated or fully relaxed state, into the imaging slice. These spins, with full equilibrium magnetization, produce a much stronger signal than stationary spins. The stronger signal creates the desired contrast between flowing blood and stationary tissues. This enhancement would be difficult to achieve with a spin echo sequence due to the flow void effect.

The TOF effect is flow velocity dependent. Thus, with the same imaging plane, regions with fast flow will appear brighter than the regions with relatively slow flow. In general, TOF MRA techniques are designed to generate positive contrast between flowing blood and background stationary tissues. There are three essential and interdependent factors for optimal use of TOF effect:

1. suppression of background tissue signal;
2. signal enhancement of moving spins with accurate spatial depiction;
3. sufficient MR image quality to properly represent both flow and surrounding structures.

There are many TOF MRA imaging sequences.[13–22] Generally, these techniques are designed to balance among the three factors for specific applications. Design
Magnetic Resonance Angiography

3

considerations are on imaging parameters, such as TR, echo time (TE), strength of the RF excitation (as specified by the flip angle), slice thickness, and flow dynamics at the region of interest. Additional design considerations include: blood vessel geometry, orientation, and surrounding environment.

The wide range of physiological hemodynamic effects results in many significant technical challenges for TOF MRA techniques. Ideal TOF effects result from constant flow and speed across a vessel perpendicular to the imaging plane. Blood, however, travels at velocities that range from near zero to about 1 m/s, and constantly changes both velocity and direction. The time duration for peak flow can be as short as a few milliseconds, then the flow may slow down and even reverse direction. With each cardiac cycle, this whole process is repeated and modulated by respiration and body motion. Blood may pass through tortuous vessels and focal narrowings that reduce the cross-section by >95%. These morphological features as well as surface irregularities, such as ulceration and atherosclerotic plaque, disturb the smooth laminar flow of blood through the vessel, and therefore complicate TOF techniques.

Another major image quality concern is the extra phase accumulated when spins move during the application of gradient magnetic fields. The phase accumulation can be described by a simple integral over time (Equation 1):

$$\Phi = \gamma \int G \cdot \vec{x} \, dt$$

where $\gamma$ is the gyromagnetic ratio, $\vec{x}$ is the physical location of spins expressed as a vector and $G$ is the magnetic gradient field applied as a function of time expressed as a vector for gradient field applied in all three axes. As a simple example, when spins are moving with a constant velocity $v$ along $x$ direction during the application of a constant gradient $G_x$ along $x$ direction for a period $T$, the phase is given by Equation (2):

$$\Phi = \gamma G_x \left( x_0 + \frac{v T^2}{2} \right)$$

where $x_0$ is the spin location at the start of the gradient application. A zero or constant phase shift will not affect the final magnitude data (MR image). For flow with variable velocity, however, the extra phase accumulated may cause image artifacts to appear as a streak of ghosting (image artifacts) along one of the data acquisition axes, as shown in Figure 3. In addition, phase distribution within a pixel may cause intra-pixel dephasing that can lead to signal cancellation.

An effective technique to deal with the effect of extra phase accumulation is gradient moment nulling. Based on Equation (2), when $v = 0$, a bipolar shape gradient (two lobes, one positive and one negative) can be easily used to set the phase to zero. If $v \neq 0$, it is possible to design a polynomial gradient shape to set the phase to zero. This approach is called gradient moment nulling. In most cases, gradient moment nulling is applied to set the phase to zero for constant flow, and can be applied to all three directions. It has been very effective even for
situations where flow velocity is a variable (see Figure 3). Generally, gradient moment nulling prolongs the TE.

Image contrast in TOF images depends on enhancing signals from flowing blood, and suppressing signals from stationary tissues. Suppression of background tissue signal can be accomplished through the use of rapid TRs (short TR), and relatively high RF power levels (high flip angle). However, the same saturation process that reduces stationary signal can also reduce signal from flowing spins. Flow enhancement, on the other hand, can be achieved by placing the imaging slice perpendicular to the direction of flow. For example, cross-sectional (axial) TOF images of the carotid artery tend to have very good flow enhancement because of the orientation of the artery and the imaging plane. For certain arteries, however, it may not be feasible to place a slice perpendicular to the flow direction.

2.2 Flow Induced Phase Shift Phenomena

The second class of flow effects arises from changes in the phase of transverse magnetization induced (of spins) as the blood moves along a magnetic field gradient.\(^{(26,27)}\) The phase accumulation is described in Equation (1). During an imaging data acquisition, magnetic field gradients are applied for short periods of time for spatial encoding. During the short period of a gradient pulse, nuclei at different locations are at slightly different frequencies. This causes the phase of transverse magnetization to change. Typically, bipolar gradients are applied so that any dephasing is compensated by a gradient of the opposite sign, so that the phase shift accumulated equals zero.

From Equations (1) and (2), it is clear that the position dependent phase shifts generated by a gradient pulse are proportional to blood flow velocity and the amplitude of the gradient pulse applied at the direction of flow. This indicates that gradient pulses can be shaped so that a desired phase shift can be achieved from moving spins while stationary tissues still maintain a zero phase shift after the gradient trains. A gradient train that satisfies this condition is usually referred to as a flow encoding gradient.

There are many different ways to design the shape of gradients for flow encoding. A typical scheme\(^{(28)}\) is shown in Figure 4. This scheme has become known as phase-contrast (PC) imaging. With the PC method, two sets of data are acquired under identical conditions, with the exception of the polarity of the flow encoding gradient pulses. Assuming constant flow \(v\), from Equation (1), the phase \(\Phi\) can be expressed in two terms:

\[
\Phi_{\text{velocity}} = \Phi_{\text{stationary}} + \gamma v TA
\]

where \(A\) is the area of each gradient lobe and \(T\) is the center-to-center time interval between the two gradient lobes. With bipolar gradient, \(\Phi_{\text{stationary}} = 0\), thus, \(\Phi_{\text{velocity}}\) is proportional to spin velocity \(v\). For subsequent acquisition, this gradient pulse inverts the polarity of the bipolar flow-encoding gradients. The phase \(\Phi_{\text{velocity}} = -\gamma v TA\). The only procedural difference in these two acquisitions is the negation of the bipolar flow-encoding gradients. This time related phase accumulation may cause intra-pixel dephasing and signal loss. Each flow encoding gradient, therefore, must have sufficient amplitude to cause a detectable phase shift in the MR signal due to flow, and yet must be small enough to minimize phase cancellation caused by velocity distribution within the imaging voxel.

There are multiple ways of extracting flow information from the imaging system. A simple example is to subtract the magnitude of the first image data set from the second. In this case, the only remaining data are from the moving spins. Alternatively, the phase of the MR signal can be extracted by complex arithmetic on the acquired data sets.

2.2.1 Velocity Encoding and Aliasing

With PC MRA, signal intensities at each pixel are proportional to the flow related phase shift, and therefore also proportional to velocity. If the phase shift is too large, however, it becomes indistinguishable from a smaller phase shift due to the \(2\pi\) range limit. This cyclical
nature of phase shift is usually referred to as aliasing. Aliasing occurs when higher flow velocities are incorrectly represented in the speed image as lower velocities due to the $2\pi$ phase shift range. To provide quantitative information regarding velocity in PC MRA, the velocity encoding (VENC) should be selected to encompass the highest velocities that are likely to be encountered within the vessel of interest. When a VENC is selected, the amplitude of the bipolar flow-encoding gradients is adjusted so that all velocities up to the selected value can be imaged without aliasing.\(^{(29)}\)

Flow encoding gradient pulses induce a phase shift in transverse spin magnetization that is proportional only to the component of velocity parallel to the direction of the applied magnetic field gradient. Consequently, an angiogram containing information for all components of velocity must be constructed from data acquired in three orthogonal flow-sensitive directions. Modern phase-sensitive pulses acquire 3D flow information using a four-excitation scheme.\(^{(28, 30, 31)}\)

PC technique is distinctly different from TOF technique, and has several features that distinguish it from other angiographic techniques as well.

1. Multiple data acquisitions with different flow encoding gradients are needed for 3D flow detection. Thus the overall scan time is longer than the TOF MRA for a similar range of coverage and spatial resolution.

2. Multiple types of images can be generated. A magnitude image can be generated that shows the anatomy, which usually has standard gradient echo image contrast. This magnitude image is generated using a complex difference method that is discussed later. A phase image shows the flow map with signals from stationary tissue removed (Figure 5). Based on this phase map, flow speed in a certain direction can be measured. In addition, image contrast is a direct reflection of flow speed and direction.

3. With PC MRA, images of high velocity blood travelling in large vessels within a large field-of-view can be acquired as easily as can slowly moving blood in small vessels. This is different from TOF MRA where image contrast reflects different levels of spin saturation. Thus, TOF MRA is sensitive to parameters such as vessel geometry and blood velocity that influence the inflow enhancements.

4. Excellent suppression of stationary tissue is possible with PC MRA because the main source of image contrast is phase shift or motion.

5. PC MRA can be used to perform quantitative velocity and flow measurements. Methods currently in use include thin-slice methods in which vessels are imaged in cross-section and the intensity of each pixel of the image is made proportional to the flow-induced phase shift.\(^{(32-35)}\)

6. Another characteristic of PC MRA is that the quality of the angiogram is heavily dependent on the quality of the instrument. In particular, the phase stability of the instrument is critical because motion is detected and quantified by measuring phase shifts in the MR signals. Eddy currents (occurring during fast switching on and off of a gradient field) are a common source of phase instability in a MR system and can lead to poor image quality.

**Figure 5** Phase and magnitude image of a normal volunteer’s carotid artery using a gated two-dimensional (2D) phase contrast imaging. (a) is the phase map and (b) is the magnitude image. In (a), stationary tissue is almost invisible due to a near zero phase. The carotid artery appears dark and the jugular vein appears bright. The darkness of the carotid artery indicates the flow direction in that artery is from inferior to superior and vice versa. In (b), artery, vein, and background stationary tissue are visualized. Note the relative positioning of the blood vessel to the background. The flow directional information, however, is not presented in this image. (Courtesy of GE Medical Systems, Waukesha, WI.)

### 3 BASIC MAGNETIC RESONANCE ANGIOGRAPHY IMAGING TECHNIQUES

There are three MRA imaging techniques: 2D/3D TOF, 2D/3D phase contrast, and cardiac gated phase contrast (these are the names used on scanners made by General
Electric Medical Systems, different manufacturers tend to use different terminology to describe the same techniques.\(^{29}\)

### 3.1 Two- and Three-dimensional Time-of-flight Techniques

TOF MRA is used extensively in the diagnosis of lumen narrowing of carotid bifurcations and of intracranial aneurysms. It is used to assess the pathologic thoracic and abdominal aorta as well as for lower extremity runoff studies.\(^{36–43}\) These techniques are most effective when “inflow enhancement” is highly pronounced. A typical example is the cross-sectional (axial) imaging of the carotid artery, where blood flow is almost completely perpendicular to the imaging plane. As mentioned in the previous section, the amount of inflow enhancement depends on several factors, including tissue specific parameters such as T1, and sequence specific parameters such as flip angle, slice thickness or blood flow velocity. The 2D and 3D techniques are illustrated in Figure 6. In Figure 6(a), a sequential 2D technique is shown that provides multiple thin sections of the vessels. Alternatively, a 3D technique can be applied as demonstrated in Figure 6(b). The whole volume is excited simultaneously, then subdivided into thin partitions or slices by using an additional phase encoding scheme in the slice select direction. Unlike 2D imaging, in which the slice resolution is defined by the excitation profile of the RF pulse, here the slice resolution is defined by the spatially encoding gradients and can be less than 1 mm thick. In 3D imaging, complete compensation for the flow-induced phase shifts is also necessary to avoid flow artifacts in the form of signal losses and ghosting. Table 1 shows a comparison of the advantages and disadvantages of 2D and 3D TOF angiography.

### 3.2 Two- and Three-dimensional Phase Contrast Techniques

PC techniques can also be divided into 2D and 3D acquisitions. 2D PC angiograms can be acquired very quickly. This makes the 2D technique useful as a localizer to determine the locations of blood vessels for detailed studies. 3D PC technique, similar to 3D TOF technique, enjoys higher spatial resolution. For the purposes of post processing, where an isotropic voxel (same size along all cubic directions) is desired, 3D PC technique has definitive advantages. This technique, however, can require a long data acquisition time. For example, when flow encoding is required along all three directions, the scan time using 3D PC can be four times longer than a 3D TOF technique that covers a comparable region. The benefits are the excellent background signal suppression, the clear depiction of vessels with fast

3.3 Cardiac-gated Two-dimensional Phase Contrast Angiography

Cardiac-gated 2D phase contrast MRA is based on cine (or time-resolved) MR acquisition methods in which TR remains constant, and cardiac gating is used to trigger the detection of images at multiple points in the cardiac cycle.\(^44,45\) The cine gradient echo pulse sequence is modified to include bipolar gradients for positive and negative flow encoding, in a fashion analogous to multi-slice 2D phase contrast. VENC is also similar to non-gated 2D PC. With this approach, data at multiple points (for example 16) in the cardiac cycle are sorted retrospectively from the scan data. Magnitude and phase images are then generated for each time point in the cardiac cycle. On the phase images, signal intensity is proportional to blood flow velocity for each phase of the cardiac cycle. The phase images also display the direction of blood flow in the same direction as the flow-encoding gradient, a dark signal indicates flow in the opposite direction. The Cine PC technique is useful for imaging pulsatile blood flow in peripheral arteries. Imaging in which thin slices are excited and the velocity-induced phase of each pixel is displayed to provide a quantitative measure of blood velocity has become widely used in the past few years. Cardiac gated PC methods have been applied in head,\(^46\) aorta,\(^47\) renal,\(^48\) mesenteric,\(^49\) and peripheral vessels.\(^50\)

4 POST PROCESSING TECHNIQUES AND BLOOD VESSEL VISUALIZATION

Post processing of MRA image data is almost a necessity in clinical applications for demonstrating spatial positioning, connectivity of vessels, and correlative MR imaging. In addition, with many MRA techniques it is possible to accumulate upwards of 100 images. There is a need to integrate the information provided by individual images and display them in the familiar form of an angiogram. This is most frequently accomplished with a maximum intensity projection (MIP) algorithm.\(^51\) The MIP algorithm, performed on a computer, finds the maximum intensity pixel along a specified projection line in all slices of a MRA data set. These maximum intensity pixels are then copied onto the projection plane, forming the projection image. With high-contrast bright blood images, the result is an angiogram. Unlike X-ray angiography, the MIP pixel signal intensities are not additive. The algorithm will only detect the maximum intensity pixel and only that pixel will be projected. Projection angles can be arbitrary. Hence the 3D MRA data set can be viewed from multiple angles for viewing purposes (Figure 7). However, some problems arise with this method. One is that the overlying vessels may complicate the view angle. Another is the lack of depth information on the projection image. There are techniques introduced to enhance the MIP algorithm and to explore other methods of processing and display.\(^52–55\)

5 RECENT DEVELOPMENTS

5.1 Contrast-enhanced Magnetic Resonance Angiography

Both TOF and PC MRA techniques are essentially non-invasive and rely on in-flow enhancement or phase shift to generate contrast between flowing blood and stationary tissues. There are several disadvantages associated with these techniques. One is in-plane saturation, which can be a problem with slow flowing or tortuous arteries. A second is turbulence-induced signal loss in a region of narrowing. Imaging times also tend to be long, especially for covering a large vasculature. Recent advances
in the implementation and understanding of 3D contrast enhanced MRA are making vascular imaging of the body safer and more accurate.\textsuperscript{58,57} This is accomplished by using paramagnetic contrast media injected intravenously. Gadolinium chelate is a paramagnetic metal ion that decreases both the spin-lattice (T1) and spin-spin (T2) relaxation times.\textsuperscript{58} These agents have been widely used to generate contrast enhanced MR images, and are also now used for angiographic images. These extracellular agents diffuse from the intravascular compartment into the interstitial space in a matter of minutes. Due to the strong enhancement effect of paramagnetic contrast media, a small dose injected as an intravenous bolus is sufficient to briefly enhance the entire arterial vascular tree. However, imaging time must be short, and timing is critical to get the desired enhancement.\textsuperscript{57,58} By using a 3D gradient echo pulse sequence on scanners with high performance gradient systems, high resolution 3D volumes of image data can be acquired in a single breath-hold. The 3D acquisition allows imaging with a large field-of-view that encompasses an extensive region of vascular anatomy. Newly deployed hardware and software on commercial scanners has vastly improved image quality of 3D contrast MRA exams. This is particularly true in the chest and abdomen, where breathing has always been a problem for imaging. Subsequent post-processing, in the form of edited maximum pixel projection, allows an angiographic display of image data in any desired obliquity. Figure 8 is an example of contrast enhanced MRA of human carotid arteries. Figure 9 is an example of contrast enhanced MRA of human abdominal region.\textsuperscript{59–62} Clinical applications of contrast enhanced MRA can be found in many different parts of the human body.\textsuperscript{63–68}

**Figure 8** A front-to-back MIP image from a stack of coronal contrast enhanced 3D TOF MRA images of carotid arteries. Phased-array carotid coils were used to improve the signal-to-noise performance of the scanner at the carotid bifurcation region. The overall data acquisition time was 40 s. A tight stenosis is delineated on the left internal carotid artery (see arrow).

**Figure 9** An abdominal TRICKS exam from a patient suffering from peripheral vascular disease. 3D TRICKS time frames were formed every 7 s after the injection of 15 mL of a gadolinium based contrast agent. Imaging parameters were: TR(ms)/TE(ms)/flip angle = 7.8/1.7/45, field of view = 48 cm $\times$ 36 cm. The peak arterial time frame demonstrates excellent depiction of the renal arteries as well as the infra-renal aorta and iliac arteries. 3D TRICKS is a time-resolved, contrast enhanced, 3D MR technique developed to image the passage of the contrast agent that: 1) increases the likelihood that an arterial-only 3D image set will be obtained. 2) Permits the passage of the contrast agent to be observed, and 3) allows temporal-processing techniques to be applied to yield additional information or improve image quality.\textsuperscript{59–62} (Courtesy of Drs. Shannon Swan and Charles A. Mistretta of the University of Wisconsin, Madison, WI.)
5.2 Coronary Magnetic Resonance Angiography

Coronary artery disease (CAD) is the leading cause of death in many countries. X-ray contrast angiography is widely accepted as the definitive method of defining coronary anatomy. This procedure, however, is associated with significant radiation exposure, and thus carries risk for potentially serious complications. Additionally, the procedure is expensive. An alternative, noninvasive technique that could reliably provide both anatomic and functional information about the coronary circulation would be an important advance in imaging. MR coronary artery angiography was attempted almost at the initiation of MR imaging. To date, however, even with significant improvement of scanner hardware, software, imaging technique and image quality, coronary MRA remains mainly a research tool used only at a limited number of institutions. The main reason is that the coronary tree is a small, convoluted, 3D structure that changes shape during heart contraction. During contraction, motion of the coronary tree involves both displacement and rotation. This motion is highly variable among different individuals depending on age, heart volume, breathing pattern, and global ventricular systolic function. In addition, there is complicated blood flow within the four chambers of the heart and in the coronary arteries. Thus, the technical challenges for imaging are to acquire high resolution images in a short time that is flow sensitive, yet motion insensitive.

Advances in hardware (gradients, receiver coils) and software (data acquisition and image processing) now allow for imaging methods that can visualize the proximal portion of the major epicardial coronary arteries in the vast majority of individuals. Although not yet standardized, current methods for coronary MRA combine fast imaging sequences with techniques for suppressing cardiac and respiratory motion. The basic technique is gradient echo, therefore the basic contrast mechanism is in-flow enhancement. Data acquisition can be divided into 2D and 3D techniques. The advantages of each technique are summarized in previous sections. For removing the motion problem, almost all the techniques rely on cardiac gating. In addition, breath holding, navigator pulses, and complicated k-space trajectory design all are used in one way or another to shorten imaging time or remove motion interference. Figure 10 is an example of using 2D breath-hold spiral technique to image the human coronary artery.

6 COMPARISON WITH OTHER ANGIOGRAPHY TECHNIQUES

MRA has become an extremely useful clinical tool. The inherent advantages of MRA include noninvasive, 3D, high resolution, flow sensitive, and no absolute need for contrast material. Before MR and ultrasonic imaging methods became available, invasive X-ray angiography was the method of choice for the visualization of all vascular anatomy. X-ray methods, however, have several undesirable properties including patient discomfort, morbidity, and cost. Ultrasonic methods are relatively safe and low cost, but are limited to a few clinical applications and are heavily dependent on the skill of the operator. A comparison of the effectiveness of techniques used for angiography is summarized in Table 3.

Like any other radiological procedure, the proper role for a non-invasive MRA study is under considerable scrutiny in an increasingly cost-conscious health care system. Clinical experience to date has shown MRA to be effective in screening and follow-up of marginal pathological conditions, and in monitoring results of therapeutic intervention. MRA has a wide variety of options and techniques for the study of flowing blood: different methods for high spatial resolution, high temporal resolution, velocity sensitization, flow...

Functional magnetic resonance imaging (FMRI) is an analytical method for measuring brain activity while it occurs. FMRI was first demonstrated in 1992, but it has since become the most popular neuroimaging method. Its temporal resolution is of the order of seconds and hence superior to positron emission tomography (PET). Its spatial resolution is on the order of millimeters which makes it superior to both PET and electrophysiological methods such as electroencephalography (EEG). Furthermore, FMRI is noninvasive in the sense that no external contrast agent has to be used. FMRI contrast is based on the intrinsic blood oxygenation changes that occur at the site of brain activity in response to a specific task. The exact mechanism that links activity and signal change is currently not well understood and is an area of active research.

FMRI is subject to many experimental difficulties, however. A vexing problem is that of physiological (heartbeat and breathing) and gross motion. Gross motion is often coupled to the presentation of the stimulus and hence especially prone to producing artefactual activation. The analysis of the experimental data is not a standard procedure at present. While past research has generally used paradigmatic methods of analysis (hypothesis testing), nonparadigmatic (data driven) methods like fuzzy clustering analysis (FCA) or independent component analysis (ICA) have become important tools.

A more complete understanding of the physiological mechanisms leading to the activation signal, and a better grasp of the proper statistical treatment of the data, are likely to increase the power of FMRI even further.

1 INTRODUCTION

FMRI is arguably the most powerful neuroimaging technique available. Its comet-like rise in the field of neuroscience may be likened to the revolution that two-dimensional nuclear magnetic resonance (NMR) spectroscopy brought about for the determination of molecular structure in the early 1980s. Indeed, it has been observed time and time again that the potential applications of nuclear magnetism seem boundless, and the development of FMRI serves as yet another manifestation of this phenomenon. FMRI has filled many white spots on the map of the human brain already,
and it continues to do so by virtue of three outstanding advantages: spatial resolution, temporal resolution, and relative noninvasiveness.

To be sure, there are many other methods of measuring brain function, each of which may be superior to FMRI in any of these aspects. For example, single neuronal recording experiments deliver a spatial resolution which is orders of magnitude better than that of FMRI. Electroencephalographic (EEG) and magnetoencephalographic (MEG) measurements are capable of a temporal resolution that far exceeds that of FMRI. And finally, many standard psychological experiments are certainly even less invasive than FMRI, but they measure brain activity only in a very superficial manner. FMRI is capable of simultaneous temporal and spatial resolution on a scale appropriate for many questions of interest. Its temporal resolution is on the order of hundreds of milliseconds to a few seconds, which is a typical timescale for performing a cognitive task. Its spatial resolution is on the order of hundreds of micrometers to a few millimeters, which is the size of typical, anatomically defined brain areas. And finally, FMRI is invasive only insofar as it uses magnetic and electromagnetic fields, which penetrate the body but have no known adverse effects. This is why FMRI is the method of choice for innumerable experiments on human brain function.

FMRI experiments are subject to numerous technical difficulties. Therefore the method has mainly been used by groups with dedicated FMRI systems. Now most problems have been solved and FMRI experiments are being performed routinely on many clinical MRI (magnetic resonance imaging) systems. Given the abundance and continuing proliferation of MRI systems, both in North America and in other parts of the world, the importance of FMRI is likely further to increase for years to come.

## 2 HISTORY

FMRI rests on a foundation of over 50 years of NMR spectroscopy. Reports of the first successful NMR experiments were published in 1946, and NMR subsequently became the premier method for the determination of molecular structure. NMR imaging was first demonstrated in 1973 in a phantom (sample). In 1976, the first image of the human body (a finger) was produced; followed in 1977 by an image of the thorax, and, in 1978, of a human head. The first clinical magnet was installed in 1981 and NMR imaging, rechristened MRI, has become a standard method for diagnostic imaging of all parts of the human body. The author estimates that there are between 10,000 and 20,000 clinical MRI machines in existence in the world.

Contrast in MRI is mostly based on the differential relaxation times of different types of tissue. FMRI is in principle not different from (clinical) MRI, since it also measures a relaxation time parameter (the apparent transverse relaxation time, \( T_2 \)). FMRI, however, generates a time course by measuring the evolution of that quantity over the course of a behavioral experiment. It was not until the late 1980s that the potential connection between this parameter and brain activity was recognized. Furthermore, technical difficulties abound in the FMRI experiment. The expected signal from an activated brain region is only approximately 3% larger than the baseline signal; hence the demands on instrumental stability are not easily met. The first functional MRI experiments were based on previous work by Ogawa and Lee and reported simultaneously by three groups in 1992 all of these experiments involved sensory stimulation tasks. The scope of experiments has far exceeded those early ones; today, many different types of brain activation are being studied, most importantly, cognitive tasks. In a different application, FMRI has moved into the operating room. Avoiding particularly important cortical structures, like speech areas, is paramount in neurosurgery; because some of these areas are anatomically ill-defined, FMRI is often the method of choice for the localization of such areas. Furthermore, intraoperative FMRI gives the opportunity to follow anatomical changes in the brain during surgery.

## 3 PHYSIOLOGICAL BASIS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING

As opposed to electrophysiological methods, like EEG, MEG, or single neuronal recording, FMRI is a rather indirect method of detecting neuronal activity in the brain. While the electrical activity of neurons is, in principle, expected to alter the magnetic properties of the surrounding tissue, this effect seems to be too small to be measured by FMRI. Instead, the FMRI signal is generated through a set of secondary effects of neuronal activity, comprised of changes in neuronal metabolism, blood flow, blood volume, and possibly other physiological parameters.

The physical quantity that is measured directly by FMRI, and hence generates the image contrast, is the apparent transverse relaxation time \( T_2 \) of water protons; the mechanism linking brain activation and \( T_2 \) is called the BOLD (blood oxygen level dependent) mechanism. FMRI can also be performed using other contrast mechanisms; however, among methods presently available, \( T_2 \) gives the highest contrast. \( T_2 \) is a time constant that describes the decay of transverse magnetization caused...
Figure 1 Mechanism of inhomogeneous broadening. Spins with different resonance frequencies acquire a phase difference; their vectorial sum decreases with time.

Figure 2 The origin of the BOLD effect. Increased blood oxygenation decreases the number of paramagnetic particles in the blood and hence increases homogeneity. Hence the $T_2$ weighted signal increases.

by the dephasing of the individual spins (Figure 1). $T_2$ contains contributions from the intrinsic transverse relaxation time and from susceptibility effects. The simplest model for the behavior of $T_2$ upon brain activation takes into account only the magnetic properties of hemoglobin, which change depending on its oxygenation state. The hemoglobin molecule binds oxygen and transports it to the cells. In its oxygenated form, hemoglobin is diamagnetic, and in its deoxygenated form, it is paramagnetic (Figure 2). Hence deoxygenated hemoglobin forms a paramagnetic center, causing local susceptibility variations and a decrease in $T_2$. The magnitude of this effect is closely linked to the nature of the vasculature within the imaging voxel; it can be predicted that (1) the signal change from tissue is a quadratic function of magnetic field strength, (2) the signal change from large vessels is a linear function of the field strength, and (3) large vessels give rise to large signal changes, up to 20%.\(^{11-13}\)

The complete physiological mechanism that links neuronal activity and $T_2$ is complex and a matter of intense discussion. The following events are currently thought to take place:\(^{14}\)

1. Immediately (tens to hundreds of milliseconds) after the onset of neuronal activation,
   
   (a) the oxygen metabolism of activated neurons increases,
   
   (b) vasodilation occurs,
   
   (c) local blood flow increases, and
   
   (d) a variety of other, nonvascular changes, such as changes in neural size, occur.

Overall, these effects tend to counteract each other with respect to the BOLD signal, and what is commonly observed is either an initial small negative dip of the BOLD signal, or no measurable change.

2. Approximately 2s after the onset of the activation, blood flow increases in excess of metabolic demand for oxygen, so that the deoxyhemoglobin concentration decreases, and the $T_2$ weighted FMRI signal increases. This is the originally observed BOLD effect.

3. Finally, after neuronal activation ceases, blood flow decreases while oxygen metabolism is still elevated, and/or vasodilation persists after oxygen metabolism has reached the rest state. Both effects lead to the commonly observed negative BOLD undershoot before the signal returns to baseline permanently.

The most prominent predictions here are the initial “dip” of the BOLD signal and the final undershoot. The magnitude of those effects is expected to be small (on the order of 0.5% of the baseline signal) compared to the BOLD signal (approximately 3% of the baseline intensity). Both effects have indeed been observed, again in a visual stimulation paradigm.\(^{15,16}\)

4 HARDWARE ASPECTS

4.1 Magnets

Since the days of the first NMR experiments, magnet technology has evolved tremendously. While the first commercial NMR magnets were room-temperature electromagnets, most magnets used today employ superconducting alloys, thereby eliminating problems of resistive heating. On the other hand, superconducting magnets have to use liquid helium as a coolant, which causes considerable operating expense. Furthermore, superconductivity breaks down at a magnetic flux density of more than 20 Tesla (20T corresponds to a proton NMR frequency of 850 MHz). This is why the strongest magnet used for NMR (like the 33T/32-mm bore magnet at the National High Magnetic Field Laboratory) is a room-temperature electromagnet; however, the power consumption of that magnet is approximately 19 MW (see National High Magnetic Field Laboratory and Florida State University, Tallahassee, 1999, www.nhmfl.gov).

The quest for higher magnetic fields in NMR spectroscopy is motivated by increased signal-to-noise-ratio (SNR) and spectral dispersion. SNR increases theoretically approximately with the magnetic field, $B_0^{5/2}$. 
Linewidths and scalar couplings are largely independent of field strength (as they depend only on the relaxation times and coupling strength, respectively), but the chemical shift is a linear function of field strength. Hence the separation of lines increases at higher fields, which makes possible, for example, the study of macromolecules.

In FMRI, on the other hand, the advantages of higher field are controversial. Spectral dispersion is not an issue here because FMRI only looks at a single resonance line (that of the water protons). SNR increases, in principle, with magnetic field strength, because the physical mechanism of signal generation is the same as in NMR spectroscopy. However, technical issues prevent us from taking full advantage of the increased SNR. Most prominent here are the decreased relaxation times in tissue. At 1.5 T, $T_2$ is on the order of 50 ms; at 4 T, it is approximately 30 ms. This means that the signal decays much faster, increasing demands on gradients and data acquisition hardware commensurately. However, the quantity of interest to functional MRI is the (BOLD) contrast-to-noise-ratio (CNR); it has been shown that CNR increases up to a field strength of at least 4 T.\textsuperscript{17}

Most MRI systems in clinical use operate at a field strength of 1.5 T, although there are many 3-T imaging systems in research use (Figure 3). There are also a few 4-T systems in existence, and two ultra-high-field human systems: a 7-T system (at the University of Minnesota) (see Figure 4), and an 8-T system (at Ohio State University). The single most important feature that distinguishes magnets for human use from those for high-resolution NMR spectroscopy is physical size.

**Figure 3** A 3-T head-only magnet in London, Canada. Note the small size of the magnet (length, 120 cm) which makes it relatively easy to site. The bore is wider at the end shown in order to accommodate the shoulders. The complete set-up also includes a patient table. (Reproduced by courtesy of John Saunders and Andrew Procca, Winnipeg, Canada.)

The bore diameter of a high-resolution magnet is typically on the order of 5 cm, which accommodates a probe for a 5-mm NMR tube. A whole body human system typically requires a bore size of at least 60 cm in order to accommodate most people. It is being recognized, however, that functional MRI concentrates almost exclusively on the head (with a few notable exceptions); hence 3-T head-only systems are becoming quite popular now. Such systems require a bore diameter of less than 40 cm or so to accommodate the head and coil and are therefore easier to build and cheaper. These magnets may be very short and are therefore easy to site (see Figure 3).

4.2 Magnetic Field Gradients and Shims

In FMRI, spatial location is encoded by magnetic field strength and hence resonance frequency. Therefore, linear field gradients are applied along the three Cartesian axes. These field gradients are produced by specialized coils that are inserted into the magnet bore. A typical specification for gradients capable of echo planar imaging (EPI) is a rise time of 150 $\mu$s to a maximum amplitude of 30 mT m$^{-1}$ (3 G cm$^{-1}$). The gradient rise time determines the imaging speed and the gradient strength determines the spatial resolution of the image. Shims are another set of specialized gradient coils. These are used to maximize the homogeneity of the magnetic field prior to any imaging experiment, with the sample or subject in the magnet.

4.3 Radiofrequency

The resonance frequency of protons at field strengths used for FMRI ranges from 64 MHz (at 1.5 T) to 168 MHz (at 4 T). The sample is excited at that frequency and the signal is received at that frequency as well. The
power used is on the order on 1 to several kilowatts. Radiofrequency (RF) is transmitted and received through RF coils specific to the body part to be imaged. In the case of FMRI, both surface coils and volume coils may be used. Surface coils exhibit higher sensitivity, but their active region may not penetrate the brain very deeply. If the brain region to be imaged is close to the surface of the head, for example the primary visual cortex, a surface coil may be the coil of choice. On the other hand, if the structure of interest is deep within the brain, for example the cingulate cortex, a volume coil will have to be used. Volume coils are all-purpose coils and may be the only coils available at many sites. Furthermore, with both improvements in imaging speed and the advancement of FMRI into the realm of psychology, experiments studying the whole brain simultaneously are becoming more common; in such experiments, volume coils (or arrays of local coils) are the only option. A surface and a volume coil are shown in Figures 5 and 6, respectively.

4.4 Stimulation Devices

Most meaningful functional imaging experiments require some kind of interaction between the subject and the environment beyond the imaging system. Presenting an auditory or visual signal in an environment of high-magnetic field comprises its own set of technical challenges. To mention only the most obvious problem, many standard experiments in psychology are carried out with the aid of computers, but a computer can certainly not be brought into the magnet room. Two-way auditory communication between experimenter and subject is necessary for safety reasons and for information about the progress of the experiment. This is often achieved through a speaker/microphone set in or near the bore of the magnet. Visual stimulation is usually implemented by one of two methods. The simpler, but less versatile method is based on the optical projection of the image from a computer situated in the operator room onto a back-projection screen in the magnet room. That screen may be in front of the magnet or in the bore. It is viewed by the subject through a system of mirrors. In a more involved method, the computer-generated image is transformed into an optical image and transmitted through a set of fiber-optic cables into liquid crystal display (LCD) goggles worn by the subject. This system allows for stereo projection and a large visual field. Auditory stimulation is achieved by sending the audio signal into a pair of specialized headphones worn by the subject. Gradient noise (which may reach 110 or 120 dB) is an important issue here; often, a combination of headphones and intubated ear plugs is used. Both visual

**Figure 6** Volume head coil. The bird cage design is the most common design for such coils. (Reproduced by courtesy of Jarod Matwi and Ian Smith, Winnipeg, Canada.)
and audio signal have to be routed through an RF filter panel into the shielded magnet room.

In addition to sending signals into the magnet room, many experiments require the recording of, or even interaction of stimulation software with, behavioral signals. For example, in one experiment a finger tapping task was investigated at high-temporal resolution. In order to characterize the signal properly, the exact timing of the finger movement had to be measured. Therefore, subjects were given a button pad with one button for each finger. Every finger movement generated a digital signal which was sent outside the magnet room and recorded by a computer. Similarly, physiological data (breathing and heartbeat) are often measured, recorded, or used to trigger gated acquisitions.

5 PULSE SEQUENCES

MRI experiments can be conveniently described in an inverse space, commonly called “k-space”. This space is analogous to the reciprocal space used in X-ray diffraction. Both in NMR spectroscopy and in MRI, the signal is acquired as a function of time and then decomposed into its constituent frequencies by Fourier transformation. In MRI, space is encoded by resonance frequency through the use of magnetic field gradients; hence Fourier transformation of the detected signal yields an image. k-Space is the space in which the signal is sampled; it has a Fourier transform relationship to physical space. The dimensionality and size of k-space is necessarily the same as that of real space; hence, in order to create a two-dimensional image with 64 x 64 pixels (for example, a slice through the head), we sample k-space in two dimensions with 64 x 64 time points.

Pulse sequences for MRI may be distinguished by the fraction of k-space that is sampled in a single excitation of the spin system. This, of course, largely determines the speed with which an image may be acquired. Not surprisingly, however, there is a tradeoff between speed (temporal resolution), spatial resolution, and SNR; hence every application may require a different pulse sequence.

5.1 Pulse Sequences to Acquire One k-Space Line per Excitation

A very common implementation of this concept is the FLASH (fast low-angle shot) sequence. After a slice selective excitation pulse, a single phase-encode gradient is applied; this gradient determines the position of the acquired signal in the phase encode dimension of k-space. This gradient is followed by the readout gradient, which first dephases the signal, then rephases it, forming an echo. The echo then corresponds to a line in k-space. The pulse sequence is, therefore, repeated N times, where N is the desired number of pixels in the phase-encode dimension. Note that this pulse sequence will produce $T_1$ weighting if the magnetization is not fully relaxed before each excitation pulse; hence, for pure transverse weighting, a long repetition time has to be employed. Repetition times for FLASH sequences for anatomic imaging are typically on the order of a few milliseconds; for functional imaging, however, $T_2^*$ weighting is required. The optimum contrast here is achieved when the echo time is on the order of $T_2^*$ (tens of milliseconds), as shown below; the time needed to acquire 64 lines of k-space for a low-resolution image is on the order of several seconds! Hence FMRI using FLASH is usually not desirable, especially if we consider that there is almost always more than one slice of interest. However, FMRI can be and has been successfully performed by FLASH, as shown in section 10 below.

Similarly, spin-echo pulse sequences may be used for anatomic imaging. These pulse sequences exhibit $T_2/T_1$ weighting, as inhomogeneous broadening is refocused by the echo.

5.2 Pulse Sequences to Acquire Several k-Space Lines per Excitation

Both gradient echo and spin-echo pulse sequences may be modified by acquiring more than one echo. An example is the fast spin echo, or rapid acquisition with relaxation enhancement (RARE) method; here the excitation is followed by a number of echoes, separated by an incremented gradient in the phase encode direction.

5.3 Pulse Sequences to Acquire the Complete k-Space in One Excitation

The fastest pulse sequences cover all of k-space in a single excitation. EPI sequences traverse k-space in a rectangular pattern (see Figure 7). Spiral pulse sequences traverse k-space in a spiral, simultaneously varying both transverse gradients. An example of a gradient-recalled echo (GRE) EPI pulse sequence is shown in Figure 8. The initial excitation pulse selects the slice of interest; the subsequent echo train then acquires the signal from that slice. The readout gradient oscillates continuously, forming an echo train, while the “blipped” phase encode gradient increments the phase between any two echoes.

Typical instrumental parameters for a high-performance system are as follows: maximum gradient strength is 30 mT m$^{-1}$; rise time to maximum is 200 µs; receiver bandwidth is 200 kHz. Note that, in EPI pulse sequences with linear sampling, the echo time is defined as the time from the first excitation pulse to the center of the echo train (32nd echo for 64 x 64 matrix size; 64th echo for 128 x 128 matrix size). As will be shown below, the optimal echo time for FMRI is on the order of $T_2^*$. 
MAGNETIC RESONANCE IMAGING, FUNCTIONAL

Figure 7 k-Space sampling trajectory for an EPI sequence. In this case, the sampling starts at the center and fills the phase-encode dimension in an alternating fashion (center-out sampling). Equally common is “linear sampling”, where the phase encode dimension is filled linearly from bottom to top. Different sampling schemes are prone to various different artifacts. (Reproduced by courtesy of Seong-Gi Kim, Minneapolis, USA.)

Figure 8 An EPI pulse sequence diagram. After slice selection, the read gradient oscillates to form the required number of echoes, while the (blipped) phase encode gradient is incremented between any two echoes. (Reproduced by courtesy of Seong-Gi Kim, Minneapolis, USA.)

which, in turn, ranges from about 25 ms (at 4 T) to about 50 ms (at 1.5 T). Hence the execution time of this pulse sequence (the time to acquire one slice) should be on the order of 100 ms at 1.5 T and 50 ms at 4 T. With the above parameters, this may be achieved at 4 T with a resolution of \(64 \times 64\) pixels; if higher spatial resolution is required, the pulse sequence must be segmented (in segmented pulse sequences, k-space is divided into several segments, each of which is sampled in one acquisition). With a high-performance 1.5-T system, a resolution of \(128 \times 128\) can usually be achieved in a single segment.

6 SAFETY ISSUES

Since the inception of MRI, the safety of the method has been intensely debated. Virtually all scientists agree that MRI is a very safe method if standard precautions are followed. Statistically, it is orders of magnitude more probable that a subject is hurt on the way to the examination, than during the MRI examination itself. It must be conceded, however, that nothing can be said about long-term side effects, because significant numbers of MRI examinations have been carried out only since about the mid-1980s.

There are several types of issue concerning safety. These may be categorized into safety issues that are integral to a standard examination and hence unavoidable and safety issues that are external to the examination and stem from improper procedures.

6.1 Safety Issues Integral to the Examination

There are three components to an MRI scan that may be the source of safety problems: the static magnetic field, electromagnetic radiation, and time-varying magnetic field gradients. Limiting values for these quantities are set by the various national regulatory bodies; in the USA, this is the Food and Drug Administration (FDA). FDA guidelines are presently (2000) as follows.\(^24\)

6.1.1 Static Magnetic Field

For routine clinical use, the static magnetic field has long been limited to 2.0 T. However, a 3.0-T head-only scanner has been approved for this purpose. For research use, approval is given on a case-by-case basis; at present, the highest field strength in use for human experiments is 8.0 T. While no study has conclusively found adverse side effects of high-magnetic fields in humans, there has been anecdotal evidence of fatigue, dizziness, metallic taste and other nonspecific symptoms in the presence of very high-magnetic fields. Evidence to the contrary, however, was obtained when subjects were asked to fill out a standard exit questionnaire after they were subjects of a mock MRI study in a nonfunctional magnet.\(^25\) The answers in the questionnaire were not significantly different from those obtained from actual experiments. However, as mentioned above, there is no well-controlled study that shows if the perceived symptoms are related to the magnetic field or not.

6.1.2 Electromagnetic Radiation

In order to excite the spin system, electromagnetic radiation is applied to the tissue in the active region of the coil. A large fraction of the energy associated with this radiation is absorbed by the tissue and may cause local heating. The permissible amount of energy is defined in terms of the specific absorption rate (SAR). There are presently two limits, either of which must be met:
1. The SAR must be less than 0.4 W kg\(^{-1}\) averaged over the body and less than 8.0 W kg\(^{-1}\) in any 1 g of tissue and less than 3.2 W kg\(^{-1}\) averaged over the head, or
2. The exposure to electromagnetic radiation must be such that it produces a core temperature increase of no more than 1 K and localized heating to no more than 38\(^\circ\)C in the head, 39\(^\circ\)C in the trunk, and 40\(^\circ\)C in the extremities. In some patients, however, these values may be exceeded.

The actual values are difficult to determine theoretically or experimentally. A common problem occurs with surface coils, where the spatial distribution of deposited power is not well-known. Consequently, experimentalists often allow a considerable margin of error for these experiments.

6.1.3 Magnetic Field Gradients

These fast-switching gradients are probably the source of greatest concern. In fact, these gradients are largely responsible for the loud noise associated with MRI experiments. Possible biological effects include the illusion of flashing lights and stimulation of peripheral nerves. One of the following conditions must be met:

1. The system is not capable of producing gradient switching rates \(\frac{dB}{dt}\) of more than 6 T s\(^{-1}\).
2. For longitudinal gradients, \(\frac{dB}{dt} < 20 \text{ T s}^{-1}\) if \(t > 120 \mu\text{s}\), or
   \[\frac{dB}{dt} < 2.4 \text{ mT s}^{-1}\] if \(12 \mu\text{s} < t < 120 \mu\text{s}\), or
   \[\frac{dB}{dt} < 200 \text{ T s}^{-1}\] for \(T < 12 \mu\text{s}\)

For transverse gradient, limits are three times lower.

3. With an adequate margin of safety, the pulse sequence in question does not cause peripheral nerve stimulation.

6.2 Safety Issues External to the Magnetic Resonance Imaging Examination

In spite of the most careful precautions, ferromagnetic objects pose the greatest danger. Such objects can accidentally be brought near the magnet; particularly common are gas cylinders and metal buckets. Near the magnet, these objects can become projectiles and seriously hurt people and damage equipment.

Metal objects inside the subject’s body can be dangerous as well. Dental fillings are usually not of concern here, especially when produced in North America or western Europe. However, other metal objects in the body (e.g. biomedical implants), or on the surface (e.g. earrings, or, in some cases, tattoos) may lead to inadmissibility. The danger represented by such objects is threefold. The objects may be dislodged if ferromagnetic and cause damage, the function of biomedical implants may be compromised and, for some geometries, currents may be induced in the object and cause heating. Hence subjects have to be screened carefully before each MRI examination, and a risk assessment has to be performed on a case-by-case basis. In the case of normal volunteers, the exclusion criteria will generally be much more stringent than in the case of a medically beneficial or necessary examination.

7 NOISE AND ARTEFACTS

As mentioned above, the BOLD effect is small (on the order of a few percent) and the signal is confounded by noise and other artefacts. (Note: in this context, an artefact is any unwanted signal.) We may conveniently distinguish between environmental noise, instrumental noise, and sample noise.

7.1 Environmental Noise

Environmental noise consists largely of electromagnetic radiation, either from ubiquitous sources, or from electronic devices in the vicinity of the MRI system; this is particularly common in a hospital environment. Environmental noise can be minimized through the use of a shielded room; signals intended to penetrate the RF shield, such as the MRI signal itself, are routed through filter panels.

7.2 Instrumental Noise

The bulk of the residual RF noise originates in the electronic components of the system itself. While this is in principle unavoidable, the design of ultra-low-noise electronic components, namely preamplifiers, is an area of active research.

7.3 Sample Noise

7.3.1 Physiological Motion

In the case of FMRI, the sample is a living system. Here the sample is arguably by far the most important source of artifacts. One extremely important source of sample noise is physiological in nature. Most prominent are the cardiac and respiratory cycles and swallowing.

Cardiac motion leads to a periodic change in blood volume, thereby affecting the BOLD signal. The frequency of this motion, however, is high (on the order of 1 Hz). In the majority of FMRI experiments, the acquisition frequency is less than 1 Hz; for example, the repetition time of a whole-brain experiment is typically on the order
7.3.2 Gross Motion

Possibly the most vexing source of sample noise is gross motion of the head. In areas of uniform intensity, motion will naturally have little effect on the signal; however, in the vicinity of large susceptibility gradients, like at the interface between sulci and gyri, near ventricles, and at the edge of the brain, gross motion will cause large signal fluctuations. Importantly, gross motion may be tightly coupled to the experimental paradigm, particularly in tasks involving overt movement of extremities or visual stimulation if the best viewing angle for the display is not in the most comfortable position for the subject. Hence gross motion may mask activation that is actually present or, which may be worse, mimic activation where there is in fact none. A single-slice or multislice experiment (as opposed to a true three-dimensional experiment) imposes a unique spatial direction on the sample; hence we have to distinguish between in-plane motion and out-of-plane motion, and also rotational and translational motion. In order to avoid erroneous measurements caused by gross motion, we have to consider four approaches, which may be used simultaneously. These are, in order of relative promise: (1) active motion correction during acquisition, (2) minimization of motion amplitude, (3) postacquisition motion correction, and (4) recognition of residual motion.

Active motion correction entails the measurement of motion and subsequent changing of gradient amplitudes in real time, such that the head remains immobile in the gradients’ frame of reference. This method is still in its infancy, but commercial devices for this purpose are being developed. The difficulty here is mainly the actual measurement of the motion with sufficient accuracy; this may be accomplished using laser beams.

The second approach largely entails immobilization of the subject. Devices that may be used for this purpose depend on the specific subject and on the nature of the experiment. The most effective immobilization devices are face masks and bite bars. Their use is not widespread, presumably because they may cause discomfort and anxiety in many subjects. Face masks are manufactured on-site from a thermoplastic material, which is heated and molded to the subject’s face; holes are usually cut out for eyes, nose, and mouth. Both face masks and bite bars are rigidly attached to a head holder, which itself is attached to the patient table. Less effective for immobilization but ubiquitously used is a set of foam pads squeezed between the inside of the head holder and the subject’s head. These can be individually adjusted for comfort; however, they restrict mainly translational motion along the magnet’s $x$-axis and rotational motion about the $z$- and $y$-axes. The motion that is most likely to occur, however, is rotation about the $x$-axis (corresponding to a nodding of the head).

For the two most common scanning directions (axial and coronal), this constitutes out-of-plane motion, which is difficult to correct for. Hence the immobilization devices used at present are unsatisfactory and will most certainly be developed further.

Postacquisition motion correction is now quite routinely performed; however, present algorithms leave much to be desired. This correction actively takes into account the nonlinear effect of motion on the BOLD signal, or it may simply “register” the image with respect to a reference position. In general, out-of-plane motion is much more difficult to correct than in-plane motion.

It very important to recognize residual motion in a data set, if only to discard the experiment or limit the conclusions that can be reached. Artifacts caused by gross motion have some specific properties that may allow the experimenter to recognize them. If there were pure in-plane motion, we would expect the total signal intensity to be approximately conserved. For linear motion, we would further expect there to be a spatially symmetric pattern of positive and negative signal changes; for rotational motion, such a pattern might still be present over short distances. In the case of out-of-plane motion (“through-plane”) motion, a similar conservation rule does not apply; furthermore, a susceptibility gradient between two adjacent planes may often not be recognized as such, unless a three-dimensional reconstruction of the image is performed.
8 EXPERIMENTAL DESIGN

As with any experiment studying brain function, proper selection of control and activation conditions is crucial in FMRI. Furthermore, the specific question asked determines parameters like the pulse sequence used, the repetition time, and the spatial matrix size. As with any modality, spatial resolution, temporal resolution, and imaging volume compete with each other. Independent of that, we may distinguish two basic experimental designs: block designs and single trial designs.

8.1 Block Designs

The fundamental difference between block designs and single trial designs is that the former measure activation as an average over the execution of many tasks, while single trial experiments seek to devolve a complex activation pattern on the timescale of a single execution of a task. A basic block design consists of a series of alternating control and stimulation periods. The length of each block is large compared to the hemodynamic response time (which is on the order of a few seconds); hence this design only requires a simple binary reference function for data analysis (see below). Block-design experiments are appropriate when the timescale on which neuronal information is sought is long compared to the hemodynamic response time.

8.2 Single Trial Designs

Single trial experiments require a different design both for experiment and analysis. The duration of a single trial of a cognitive task may be a few seconds. If meaningful temporal characteristics of neuronal activity are to be determined on the timescale of a single trial, the finite hemodynamic response has to be taken into account. Several approaches have been used in the past: an “averaged single trial” method, a mixed-trial technique, and a true single-trial technique.

In the averaged single trial method, FMRI signal acquisition is gated by the onset of the presentation of some task, independent of behavior. That approach is permissible in the limit where behavior and brain function do not vary significantly over repeated trials; this may limit the applicability to some experiments. In addition, insofar as intrinsic hemodynamic responses may be different in different regions, information about temporal differences in neural activity is necessarily limited. Thus comparing time courses across functionally specialized regions is sometimes problematic. Sequential neuronal activity cannot be easily determined simply from the difference in onset times in single averaged time courses. In spite of this difficulty, however, this approach is extremely valuable if information is sought on a temporal scale that is more coarse than the variations in hemodynamic response times.

The mixed-trial technique uses a sequence of random stimuli presented in rapid succession; the data are then analyzed by correlating the responses to the specific sequence pattern of each individual stimulus type. This method makes it possible to assign activation in different areas of the brain to different tasks or aspects of a task, but, again, the temporal resolution is limited to possible differences in hemodynamic response times between regions.

In the true single trial “time resolved” technique, hemodynamic response time differences between regions are canceled through the use of multiple individual trials, as shown in Figure 9. A task with a varying temporal parameter is carried out several times and the variation of the hemodynamic response is correlated with this variable parameter. In this manner, the unknown hemodynamic response time is canceled and activation may be assigned to an aspect of the task that does or does not vary with reaction time. This method was used for an investigation of Shepard and Metzler’s mental rotation task; it was found that the superior parietal lobe and motor areas are involved in the very act of mental rotation.

Because no averaging over several executions of a task is performed in time-resolved single trial FMRI, SNR can be poor. Thus, this method may often not be feasible, particularly at low-magnetic fields. This approach permits the determination of the specific function of given brain areas in the context of a single complex task, unlike methods that use indiscriminately averaged single time courses.
9 DATA ANALYSIS

The analysis of FMRI data is far from being a routine procedure. On the contrary, data analysis in itself is presently an area of intense research. The generic question that FMRI tries to answer may be, “What is the activity in the brain that generates a certain behavior?” There are two obstacles to answering this question. The first obstacle concerns the relationship between neuronal activity and the BOLD signal, which is not well understood at present. The second obstacle is the measured signal, which is different from the actual BOLD effect, as it is discrete in time and contaminated by noise.

The physiological origin of the FMRI is unclear, as discussed above, so that we cannot uniquely deduce brain activity from the time course of the BOLD signal in a given area. Conversely, we cannot accurately predict the time course from a postulated neuronal activity. In most FMRI experiments, this problem is simplified by the following implicit assumptions:

1. The activation state is a binary physical quantity; that is, a given area of the brain is either active or not active in relation to a task. A corollary of this statement is that, on the timescale of most experiments, activation is immediately switched on and off; it is further assumed that the BOLD signal shows the same behavior, though possibly after a (predictable) delay.
2. The location of the BOLD signal is indeed the location of activity, within the spatial resolution of the experiment.
3. The BOLD signal in distributed areas of the brain exhibits linear behavior; that is, the signal in one area is independent of that in the other areas.

The first assumption may be valid as long as the required temporal resolution is lower than the rise time of the hemodynamic response (a few seconds). For whole-brain studies, this is generally the case; however, if a specific area is to be investigated separately, we may want to scan as fast as 100 ms per imaging volume. In that case, the actual shape of the hemodynamic response may have to be taken into account. This is discussed further below.

The validity of the second assumption, again, depends on the required resolution. The BOLD signal is likely to contain both a metabolic and a flow component. The metabolic component is necessarily localized very close to the actual site of activation. This is why it is thought that the initial decrease in the BOLD signal, which is metabolic in nature, may give better spatial information than the conventional (positive) part of the BOLD signal. The flow component of the signal, on the other hand, may originate several millimeters distant from the true locus of activation.

The third assumption, concerning spatial linearity, is possibly the least well explored. It is likely that this assumption is never strictly valid, as the brain is never “quiet”, even during a so-called baseline condition. However, within the limits of our measurement and with clever task design, the assumption may often be valid for our purpose at present.

9.1 Paradigmatic Methods

A first-order approximation to the FMRI signal is that it is binary both in space and in time. This means that a given pixel is either active or not active at any given time. In space, the binary nature is dependent on voxel size; in a large voxel, we have to allow that an activated area only partially occupies a voxel (this is commonly called the “partial volume effect”, which is a misnomer, because partial quantities are generally residual nonlinear effects). The signal intensity of that voxel will be the average of that of a quiet voxel and that of an activated voxel; therefore the relative signal change will be decreased and the voxel may or may not be found to be activated. This issue is essentially only important when voxels are large, which may be the case especially in the direction normal to the slice. In time, the binary nature of the signal is dependent on the acquisition frequency, as discussed above.

With these approximations, we are able to calculate easily a paradigmatic map voxel-by-voxel. The (usually implicit) null hypothesis for this calculation is that there is no temporal correlation between the time course of a given voxel and a behavioral vector. By inference, this means that that voxel is not significantly activated. The behavioral vector is usually derived from the presentation of the paradigm, or from the response of the subject. A common vector that is used consists of three baseline periods, separated by two activation periods. In a simple visual paradigm, for example, the visual stimulus would be turned on and off synchronously with this vector. Then, the correlation coefficient for each voxel time course with the behavioral vector is calculated. Commonly, Pearson’s (linear) correlation coefficient is used, although robust (rank) correlation methods may sometimes be useful.

The proper threshold for such a correlation map is a matter of debate. Since this is a parametric method, we may expect both type I and type II errors. The type I error rate is given by the confidence interval that can be estimated from the correlation coefficient by, Equation (1)

\[
p = 1 - \frac{2 \sqrt{\pi}}{\sqrt{N}} \text{erf} \left( \frac{cc}{\sqrt{N}/2} \right)
\]  

(1)
where \( p \) is the confidence level for the null hypothesis or the false positive rate, and \( cc \) is the correlation coefficient. This is strictly true for Gaussian noise and a good approximation for FMRI.\(^{(35)}\)

The question remains what is the proper \( p \)-value for this experiment? In experimental science, a commonly used number is 0.05, allowing 5% false positive measurements. In the present case, however, we are performing a voxel-wise test and hence are making a multiple comparison. Indeed, each voxel represents a separate experiment in a statistical sense. Suppose we are performing an experiment on the whole brain, with \( 64 \times 64 \times 35 \) matrix size (35 axial slices of thickness 5 mm would cover an average brain). There are on the order of \( 10^5 \) voxels in this volume. Hence a \( p \)-value of 0.05 would yield 5000 erroneously active voxels. Even if we consider that the brain, being an irregular body, typically occupies considerably less than half of the imaging volume, we are left with a number of type I errors that even exceeds the number of voxels that we expect to be truly activated.

An extreme solution to this problem is to apply the Bonferroni correction. In this correction, the \( p \)-value is reduced so that the probability of even a single type I error is small. In this case, we would divide the \( p \)-value by the number of voxels in the brain, which would yield a very small number. However, while this conservative procedure eliminates type I errors, it creates a large number of type II errors, and the experimenter may be left with no activated voxels altogether.

Better solutions to the significance problem take into account information beyond the time course of each voxel. This information is usually spatial, complementing the temporal information obtained from the time course. Spatial information is virtually always used implicitly, when the researcher looks at the map and decides which activated voxels “make sense” (coincide with a prior hypothesis about the location of activation). Naturally, this is hard to quantify and depends largely on intuition. A more objective approach is to use spatial clustering. The expectation here is that the volume of activation is significantly larger than the volume of a single voxel; hence true activation would produce at least two contiguous activated voxels. If \( p_1 \) is the probability of a type I error, then the probability of two type I errors in contiguous voxels is given by Equation (2)

\[
p_2 = p_1[1 - (1 - p)^{26}] \tag{2}
\]

since each voxel in the interior of the volume has 26 nearest neighbors. This, of course, does not make a distinction between neighbors that share a face, an edge, or a corner; the contiguity of the latter two in this context is certainly a matter of debate.

From Equation (2), we find for \( p_1 = 0.05, p_2 = 0.04 \); for \( p_1 = 0.01, p_2 = 0.002 \); and for \( p_1 = 0.001, p_2 = 3 \times 10^{-5} \). Clearly, with a \( p \)-value of 0.05, the requirement of spatial contiguity does not add significantly to our confidence. However, when lower \( p \)-values are used, spatial clustering improves the confidence level significantly; we can also require more than two contiguous active voxels to accept an activation in order to increase further our confidence interval. Hence, if we assume that the volume of true activation is always large compared to the voxel size, we increase our confidence interval without increasing the type I error frequency by spatial clustering.

An added difficulty is faced when the temporal resolution of the experiment is such that the rise and fall of the hemodynamic response has to be taken into account. The success of parametric methods now depends on the quality of the model function employed for the hemodynamic response. Various functional forms have been used for this purpose. One group\(^{(36)}\) used a Gaussian function with two variable parameters (“lag” and “dispersion”) in order to extract temporal information from a given area. Another group\(^{(37)}\) used a set of gamma functions to model the hemodynamic response. Yet another group\(^{(31,32)}\) employed a set of trapezoidal reference functions with four variable parameters: onset time, rise time, plateau time, and fall time. It must be kept in mind, however, that it is not necessarily advantageous to describe the hemodynamic response function more accurately as possible, because this function may be variable across different areas of the brain. It is more appropriate to use a function which, with several variable parameters, does equal justice to all possible hemodynamic response functions.

### 9.2 Non-parametric Methods

Parametric methods are only appropriate if the temporal response to the stimulus is known. As technology improves, however, we would like to measure brain activity on a timescale shorter than the usual hemodynamic response time (that is, a few seconds). In fact, temporal information about neuronal processes in the subsecond range is just becoming available to FMRI. On this timescale, the hemodynamic response is not well characterized. Furthermore, we would often like to measure neuronal activity that is not obviously coupled to an external stimulus (“spontaneous” activity); a notable example is brain activity during epileptic seizures. In such cases,
nonparametric methods are needed, which organize a set of time courses without regard to a paradigm.

A variety of nonparametric methods for FMRI data analysis have emerged. The three most prominent methods are principal component analysis (PCA), ICA, and FCA.

9.2.1 Principal Component Analysis

This method was introduced for neuroimaging data analysis in 1991.\(^\text{38}\) In PCA, the data set is reorganized into eigenimages, where the first eigenimage contains the largest variance between pairs of voxels. For this method to be successful, the task-related signal has to be indeed an important source of variance in the data. This is not always the case, particularly in the presence of physiological noise or gross motion.

9.2.2 Independent Component Analysis

ICA has been applied to FMRI data analysis.\(^\text{39}\) In ICA, the data set is organized into individual component processes; it is assumed that the component processes are spatially sparse (yielding focal activation maps) and spatially independent of one another. It has been shown\(^\text{39}\) that this method is superior to PCA and correlation analysis for one on/off paradigm; however, the above-mentioned assumptions may not be true for all experiments.

9.2.3 Fuzzy Clustering Analysis

FCA\(^\text{40,41}\) is an application of Bezdek’s original algorithm.\(^\text{42}\) Here a data set of \(N\) time points spans an \(N\)-dimensional space; each voxel time course is represented by a vector in that space. Voxel time courses are then grouped (clustered) by their proximity in that space; it is assumed that activated voxels behave sufficiently similarly to one another and sufficiently dissimilarly from other voxels that they will fall into small clusters. Examples of this method will be given below.

10 EXAMPLES OF APPLICATIONS

Since 1992 there has been an explosion in applications of FMRI; they are too numerous even to make an attempt to catalog completely. A literal definition of the scope of FMRI would encompass all physiological functions; in this sense, for example, a measurement of blood flow at rest would be categorized as FMRI. However, a more sensible operational definition is that FMRI measures neuronal activity, albeit through secondary effects like blood flow or the BOLD effect. This will be taken as the common property of all FMRI applications.

10.1 Sensory Tasks

The first FMRI experiments were carried out using visual stimulation.\(^\text{8–10}\) There are several reasons for such a choice. Compared with other sensory modalities, the visual system occupies a large area of the human brain; hence we expect multifocal activation even with a simple visual task. Visual stimulation is relatively easy to achieve with commercial goggles or a back projection screen (see section 4), and is not prone to motion artifacts.

Figure 10 shows visual activation induced by a full-field black and white flashing checkerboard. The rest

Figure 10 Activation in visual cortices from a flashing checkerboard paradigm. (Data are reproduced by courtesy of Keith Thulborn, Pittsburgh, USA; analysis is reproduced by courtesy of Ray Somorjai and Mark Jarmasz, Winnipeg, Canada.)
condition here consisted of a dark screen with a central fixation point.

Figure 11 shows a sagittal magnetic resonance image of the medial right hemisphere of the visual cortex, demonstrating ODCs.

In Figure 12, results from another visual stimulation experiment are shown. In addition to the BOLD signal, cerebral blood flow (CBF) and cerebral metabolic rate of oxygen (CMRO₂) are measured. Note that hot spots in the CBF and CMRO₂ maps correspond well with one another, while hot spots in the BOLD map are alienated from the former two.\(^{(43)}\)

Figure 13 shows activation during auditory stimulation. Figure 14 shows results from a tactile stimulation of forehead and chin. Note how forehead stimulation produced more inferior activation along the postcentral gyrus relative to chin stimulation, consistent with...
an inverted face representation of the somatosensory homunculus.\(^{(44)}\)

## 10.2 Movement Tasks

A common problem for tasks involving overt movement is gross motion of the head (see section 7). Therefore, many movement tasks involve only finger movement, which does not generally lead to excessive head movement. An example is shown in Figure 15.\(^{(31)}\) The task is a delayed finger movement task. The subject is shown four circles on the screen. During the instruction period, the four circles in the bottom row light up in a particular order (e.g. 1–2–4–3). The subject remembers this order during a variable delay period (between 0 and 7 s). Then, the upper circle lights up, serving as the “Go” signal, and the subject presses the four buttons on a button pad.
in the prescribed order. Activation is seen in various motor areas (lateral premotor area (PM), supplementary motor area (SMA), and primary motor cortex (M1)). The time courses shown are from a single trial of one subject. Activation can be seen in all three areas during the delay period and during the execution period. The absence of movement during the delay period is monitored by EMG (electromyography) recording on the forearm. Note the exquisite temporal resolution of this experiment that permits the distinction between two separate components of a task (movement preparation and movement execution).

Figure 16 shows another finger movement task. After a rest period (10 volumes), the right hand starts moving. From time index 21 to 30, the movement is bimanual, and from 31 to 40, only the left hand moves. The data is analyzed by FCA (see section 9). Note how the right and left motor area are properly separated by this method. There is another cluster (not shown) that shows activity only during the bimanual movement period.

10.3 Cognitive Tasks

Figure 17 shows activation from a cognitively demanding finger movement task. In this case, the subject is asked to perform a series of sets of four finger movements without pattern repetition (i.e. 1234, 1423, 1243, etc.). In addition to motor areas, cingulate cortex and dorsolateral prefrontal cortex are active. Note that

Figure 18 Activation map from a mental rotation task. Note the activity in frontal motor areas during a task that does not involve overt movement.

Figure 19 Activation during silent word generation. (Reproduced by courtesy of Stefan Posse, Jülich, Germany.)
this experiment is performed by FLASH imaging (see section 5).

Another cognitive task is Shepard and Metzler's mental rotation task.\(^{32,34}\) Subjects are shown drawings of pairs of three-dimensional objects which are rotated with respect to one another. They then have to decide if the two objects are identical. It has been conjectured that the subject mentally rotates the two objects into congruence. Figure 18 shows the activation map from such a task; it can be seen that areas of the parietal lobe as well as frontal motor areas are active here.

In Figure 19, activation during a task involving silent word generation is shown.

### 10.4 Other Experiments

Figure 20 shows spontaneous activation in an epileptic patient during seizures. This is an excellent example of the use of paradigm-free methods (in this case, FCA) which are essential when there is no clear expectation of the time course of activation.

FMRI is not necessarily limited to the brain. Figure 21 shows time courses from activated pixels in the spinal chord during a hand movement paradigm. Spinal cord FMRI poses its own unique challenges, because the area to be imaged is very small and very prone to motion artifacts.

11 COMPARISON WITH OTHER METHODS AND OUTLOOK

At present, FMRI occupies a prominent position among the various methods of studying brain function. Electrophysiological methods (for example, EEG or single neuronal recording) excel with a temporal resolution of milliseconds. In the case of EEG, however, the spatial resolution is centimeters at best and single neuronal recording studies, while extremely accurate in time and space, can only cover a very small number of neurons, and this only in animals or human patients. Older neuroimaging methods, like PET or single photon emission computed tomography (SPECT) generally fall behind FMRI both in temporal and spatial resolution.

Many issues in FMRI are unresolved at present. Most important here is that the physiological basis of the coupling between neuronal activity, oxygen consumption, blood flow, and the BOLD effect is not well understood. These questions are under intense scrutiny by some of the best research groups in the world and a better understanding of these effects will almost certainly lead to applications of FMRI with a spatial resolution on the order of hundreds of micrometers, and a temporal resolution on the order of hundreds of milliseconds.

The increasing availability and quality of MRI machines primarily for diagnostic purposes is likely to help FMRI to remain the foremost neuroimaging method in the near future.

ABBREVIATIONS AND ACRONYMS

- BOLD: Blood Oxygen Level Dependent
- CBF: Cerebral Blood Flow
- CMRO$_2$: Cerebral Metabolic Rate of Oxygen
- CNR: Contrast-to-noise-ratio
- EEG: Electroencephalography
- EMG: Electromyography
- EPI: Echo Planar Imaging
- FCA: Fuzzy Clustering Analysis
- FDA: Food and Drug Administration
- FLASH: Fast Low-angle Shot
- FMRI: Functional Magnetic Resonance Imaging
- GRE: Gradient-recalled Echo
- ICA: Independent Component Analysis
- LCD: Liquid Crystal Display
- M1: Primary Motor Cortex
- MEG: Magnetoencephalographic
- MRI: Magnetic Resonance Imaging
- NMR: Nuclear Magnetic Resonance
- ODC: Ocular Dominance Column
- PCA: Principal Component Analysis
- PET: Positron Emission Tomography
- PM: Premotor Area
- RARE: Rapid Acquisition with Relaxation Enhancement
- RF: Radiofrequency
- SAR: Specific Absorption Rate
- SMA: Supplementary Motor Area
- SNR: Signal-to-noise-ratio
- SPECT: Single Photon Emission Computed Tomography

1 INTRODUCTION

NMR spectroscopy or MRS is a technique of vast potential. It is a powerful, nondestructive technique that can be used to determine the complete structural and conformational analysis of complex molecules, as well as the quantitative analysis of complex mixtures. NMR involves the absorption or emission of RF energy by nuclei in a magnetic field. The higher the magnetic field used, the greater is the detection sensitivity of the instrument.

High-resolution NMR has been widely used by scientists to characterize chemical compounds. The narrow resonances reveal fine structure due to spin–spin splitting, and a wide variety of chemically shifted resonances reveal the type and number of nuclear species. To illustrate, the sensitivity of NMR to chemical structure, the $^1$H-NMR spectrum of ethyl benzene is shown in Figure 1. The spectrum contains individual groups of resonances due to the CH$_3$, CH$_2$, and aromatic protons. Integration of the areas under the multiplets yields the relative number of protons in each group, namely 3:2:5. The spin–spin splittings of the resonances indicate that the CH$_3$ and CH$_2$ groups are adjacent. The splittings of the aromatic protons are more complex, due to the similar magnitudes of the splittings and the differences in chemical shift of the types of protons – a so-called second-order spectrum. Multiple-dimensional NMR spectroscopy, in which one NMR parameter is portrayed along one axis, others along the other axes, have greatly aided the resolving power of NMR in complex situations. The most useful of these is correlated spectroscopy (COSY), where the chemical shifts of different resonances in a spectrum are correlated. More detailed discussions of the origin of NMR spectra are available.\textsuperscript{1–3} In addition to $^1$H, there is a variety of nuclei useful for biomedical applications. These are shown in Table 1 with their relevant detection properties. Their usefulness decreases in the order $^1$H, $^{31}$P, $^{13}$C, $^{23}$Na, $^7$Li, $^{87}$Rb, $^{19}$F, $^{15}$N.

Applications of high-resolution NMR to biomedical problems were hindered by the common view that the spectra would be difficult to obtain, the resonances would be broad, and overlaps of many broad resonances would make the spectra difficult to interpret. This has proved to be quite incorrect, and high-resolution NMR has been very successfully applied to biological fluids, tissue ex vivo, and living organisms.

One reason for this success was the rapid increase in availability of NMR instruments operating at high magnetic field. Detection sensitivity increases with the magnitude of the applied magnetic field, from linearly to the I.75 power, depending on the nature of the specimen\textsuperscript{(4)} (Table 2). Concomitantly, the spectral separation in hertz between chemically different species...

Some of the earliest applications to complex biomedical systems were made in the 1970s, principally with 31P NMR. A long period followed with emphasis placed on microorganisms and cell extracts. The observation of well-resolved 31P spectra from humans in vivo stimulated a new interest in NMR of tissue. NMR of biofluids evolved slowly but steadily during this time. Applications of high-resolution NMR in clinical and pharmaceutical chemistry as well as NMR of tissue have been reviewed.

1.1 Biological Fluids

A large number of biological fluids is accessible for MRS study ex vivo. Early applications of 1H-MRS analysis demonstrating its utility involved analysis of urine and serum. A large number of other biofluids, including cerebrospinal fluid (CSF), amniotic fluid, synovial fluid, seminal plasma and bile, and tissue extracts have since been examined. 1H-MRS analysis of biofluids offers several advantages: it requires little or no preparation of the sample; high-quality spectra, suitable for quantitative measurements, may be obtained in under 15 min; potentially all 1H-containing metabolites (including acids, bases, and neutral compounds) may be measured by applying a suitable spectroscopic technique; and the possibility of studying simultaneously, in a single measurement, all of the more usually represented metabolites without any test preselection.

Biological fluids contain compounds of interest at relatively low concentrations in water. The 1H resonance due to water is roughly 10^6 times more intense than the resonance of the compounds of interest. This creates a serious problem of dynamic range. Two approaches to resolve this difficulty have been applied. One is the increasing dynamic range of the analog-to-digital convertors (ADCs), reaching values as high as 32 bits (2^32 = 4.3 x 10^9, a significant range of discrimination). Furthermore, it has been found that saturation of the H2O resonance by simple irradiation, or by a variety of pulse sequences, serves to suppress this resonance to tolerable amplitudes. One or both of these methods may be applied.

increases linearly with the field. A wide variety of multinuclear and multidimensional techniques have led to increased sensitivity and spectral simplification. Finally, the increasing megahertz available per unit cost has made the accessibility of high-field NMR much greater.
A second problem is the wide variety of compounds present in biological specimens. The high magnetic fields presently available, up to 19 T (800 MHz for \(^1\text{H}\)), serve to diminish this problem to a tractable one.

A further problem is the simultaneous presence of species of high and low molecular weight. High-molecular-weight species rotate slowly, and thus have very broad resonances which may obscure those of the low-molecular-weight species. Fortunately, broad resonances are usually indicative of short transverse relaxation times (\(T_1\)), and these may be used in data manipulation to remove the confounding effect of the resonances due to high-molecular-weight species such as proteins, nucleic acids, and membrane lipids. This is demonstrated in Figure 2, where manipulation of the free induction decay leads to total suppression of the broad resonances due to proteins in plasma.

![Figure 2](image)

**Figure 2** \(^1\text{H}\)-NMR spectrum (360 MHz) of human blood plasma; the strong resonance due to \(\text{H}_2\text{O}\) has been reduced by irradiation at its frequency before commencing the spectral acquisition: (a) with no spectral manipulation; (b) after multiplication of the free induction decay by a sine-bell function to minimize broad resonances.

1.2 Biological Tissue

For many years it was believed that NMR of tissue was a hopeless pursuit. The seminal article by Mountford et al.,\(^{26}\) demonstrating \(^1\text{H}\) spectra of good resolution from the mammary tissue of rat, stimulated a resurgence of interest. High-resolution \(^1\text{H}\) spectra (360 MHz) of human colon tissue were reported. The transverse relaxation times (\(T_2\)) of the lipid \(\text{CH}_2\) resonance at 1.3 ppm appeared to be indicative of the metastatic potential of the hyperplastic tissue. The race was on! Since this initial observation, a wide variety of studies has been reported on human tissue ex vivo, suggesting that the high information content of the spectra should lead to effective clinical use of NMR in vivo.

Tissue differs drastically from biological fluids in that it is macroscopically solid. This leads to difficulty in optimizing the homogeneity of the applied magnetic field for optimal spectral resolution. A technique has been reported that minimizes this problem.\(^{27}\) Figure 3 shows the positioning of a piece of human tissue within a capillary tube facilitating the optimization of field homogeneity and allowing an estimation of the volume of the specimen. This method has been used in most quantitative studies to date.

Ex vivo tissue is not dead tissue; it has, however, begun a progression toward death. In studies of human tissue ex vivo, great care must be taken to ensure that the spectra of the many specimens are taken at similar times after removal from the host. One way to ensure this is to freeze the samples at liquid \(\text{N}_2\) temperature within minutes of excision. These frozen...
specimens are stable for weeks. Likewise, a rigid protocol for warming the specimens and obtaining their spectra must be followed.

NMR spectra contain a wealth of information – some vital, some useful, some useless. It is often difficult to decide by visual inspection which regions of the spectra will be most useful in classifying the specimens. Ratios of peaks can be useful, but much time must be spent before the most useful ratios are found. In our experience computerized methods to select the most discriminatory region, and to perform the classification, are robust and accurate. The most exhaustive application of these methods is described in Somorjai et al. (28) Recently, a description of the regional selection process has appeared.(29)

For spectral classification, multivariate analysis has proved to be very effective. A variety of methods, such as linear discriminant analysis, quadratic discriminant analysis, neural networks, and genetic algorithms may be used. Very often the simplest method, linear discriminant analysis, is sufficient. In the most difficult cases, a number of methods may be used and finally entered into a meta classifier.(28)

It is crucial that the NMR spectra be adequately prepared for the classification process. They must be normalized for area, adjusted for chemical shift, and the most discriminatory regions determined. Data must be divided into a training set, in which the method is calibrated, and a test set, in which the accuracy of the method is tested. Regrettably, this has been done very rarely in the literature to date, yielding promising results but with a method that is not robust. To enhance robustness, the leave-one-out method should be implemented. The procedure is challenged by leaving out one data set, classifying it by exposure to the existing classifier, leaving another out and classifying it, until all data sets have been thus treated. Finally, a sufficient number of data sets must be used if the classifier is to be accurate, specific, and robust. The number required depends strongly on the types of spectra compared.

Using the procedures described above, experimental results from which no obvious discriminators can be seen, and in which there is a wide variation in spectra from a given class, can be accurately classified. The reader is referred to the articles in this Encyclopedia which deal with chemometrics encompassing some of the same techniques (Chemometrics; Classical and Nonclassical Optimization Methods; Clustering and Classification of Analytical Data; Multivariate Calibration of Analytical Data; Second-order Calibration and Higher). The remainder of this article presents an overview of the medical applications of high-resolution MRS ex vivo. Specifically, progress has recently been made towards the diagnosis of inborn errors of metabolism, the measurement of renal injury, diagnosis of neurological disorders, and cancer diagnosis.

2 DIAGNOSIS OF INBORN ERRORS OF METABOLISM

High-field 1H spectroscopy of biofluids offers great potential for furthering the understanding of disease processes in humans. Historically, one of the most successful clinical applications of MRS has been the detection of a large number of metabolic disorders. In these disorders, the reduction or absence of activity of an enzyme or cofactor can have dramatic consequences for metabolism and its control. Many inherited metabolic disorders result in the accumulation of large amounts of organic intermediates produced proximal to the defective enzyme step, which eventually spill into the blood and urine. 1H-MRS has been used to study the urinary excretion of such compounds. Initial studies demonstrated the ability to diagnose a number of metabolic disorders including histidinemia, citrullinemia, argininosuccinic acid lyase deficiency, ornithine carbamoyl transferase deficiency, cystinuria, oxalic aciduria, alkaptonuria, multiple acyl CoA dehydrogenase deficiency (glutaric aciduria type II), methylmalonic aciduria, propionic aciduria, porphyria, 5-oxoprolinuria, homocysteinemia, trimethylaminuria, and Fanconi syndrome.(33)

More recently, both 1H- and 13C-MRS have been used to identify and quantify the presence of elevated levels of galactonate in the urine of 27 patients with uridylytransferase-deficient galactosemia. 750 MHz 1H-NMR spectroscopy has also been used recently to examine the elevated levels of 2-hydroxyglutaric acid in the urine of a patient with the rare condition of 2-hydroxyglutaric aciduria. Maschke et al. reported the use of 1H-MRS (300 MHz) for the analysis of trimethylamine (TMA) in the urine of a patient with trimethylaminuria and of other members of his family. In this study, 300 MHz 1H-NMR spectroscopy was shown to have sufficient sensitivity, resolution, and linearity to allow the diagnosis of trimethylaminuria in a classical one-dimensional spectrum of the urine of the patient (Figure 4). Moreover, this technique is easier than the established classical biochemical methods that primarily use gas chromatography. The increased TMA signal, and the decreased trimethylamine-N-oxide (TMAO), as compared to a normal healthy subject, are clearly seen at 2.90 ppm and 3.27 ppm, respectively.
Although urine appears to be the specimen of choice for the diagnosis of inborn errors of metabolism, the use of CSF has also been reported. Derangements of organic acid concentrations in CSF may occur independent of the systemic metabolism, and thus, analysis of metabolites in CSF may be important in the diagnosis and follow-up of these patients. Figure 5 shows examples of the diagnostic power of $^1$H-MRS, for relevant parts of the spectra from CSF samples of patients with isolated 3-methylcrotonyl-CoA-carboxylase deficiency, Canavan disease, and histidinemia.

A significant amount of data in the literature indicates that $^1$H-MRS of urine, and possibly of CSF, is capable of diagnosing a vast number of inborn errors of metabolism. MRS not only provides information on endogenous biochemical processes, but is also capable of rapid quantitation of metabolites, using a small volume that requires little pretreatment. Furthermore, it is not necessary to preselect the metabolites of interest, as the technique allows simultaneous measurements of a range of components. There exists also, the possibility for the detection of some novel markers of these diseases, or insights into the underlying defects of these disorders.

**3 MEASUREMENT OF RENAL INJURY**

Early studies of $^1$H-MRS of urine demonstrated that in situations where renal damage is present, the urinary profile of the low-molecular-weight metabolites is altered.
Furthermore, in studies of the effects of region-specific nephrotoxins, the application of $^1$H-MRS urinalysis indicates that abnormal patterns of metabolites are associated with different sites of nephrotoxic actions. Renal proximal tubular toxins cause glycosuria, lactic aciduria, and amino aciduria; renal papillary toxins produce abnormal excretion patterns; and renal papillary necrosis produces an initial increase in TMAO and dimethylamine (DMA) excretion followed by a subsequent increase in $N,N$-dimethylglycine, succinate, and acetate, and a decrease in TMAO and 2-oxoglutarate.\(^{47,48}\)

This information is useful when assessing renal disease progression or nephrotoxicity associated with therapeutic agents. Subsequently, $^1$H-MRS urinalysis has been used as a noninvasive diagnostic technique for tubular and papillary distortions in glomerulonephritis.\(^{49,50}\) and for the assessment of the degree of chronic renal failure.\(^{51}\)

The abnormal urinary excretion of specific enzymes and proteins as possible markers of renal allograft rejection has been studied extensively,\(^{52,53}\) and found to be relatively nonspecific. Foxall et al.\(^{54}\) used $^1$H-MRS to investigate the pattern of metabolic changes associated with renal allograft dysfunction. As shown in Figure 6, the spectra of normal human urine showed signals for creatinine, glycine, citrate, alanine, lactate, and $N$-methylated metabolites in the chemical shift range of 3.1–3.3 ppm. The spectra of patients’ urine collected following renal transplantation were considerably different. Compared to normal urine, the spectral pattern of urine from patients with an immediate functioning graft, urinary tract infection, renal tubular ischemia or with a nonfunctioning graft are widely different. Further studies associated an increased excretion of TMAO with biopsy confirmed acute graft rejection.\(^{55}\)

Thus, unlike the excretion of enzymes or proteins, $^1$H-MRS provides both diagnostic and prognostic information.

As urine has been studied most extensively, a large number of the resonances in the spectrum of normal human urine have been assigned. The aim of a recent study was to standardize the analytical conditions, to quantify the major metabolites present in urine of normal subjects, and to evaluate changes due to physiological conditions such as feeding.\(^{56}\) In this study, $^1$H-MRS, operating at 300 MHz, studied serial urine samples from 50 normal subjects. In all specimens, creatinine, lactate, alanine, citrate, DMA, TMAO, glycine, and hippurate were found to be present. All metabolites were quantified on the basis of peak heights and were expressed as millimoles per mole of creatinine. The study of metabolic profiles in serial samples allowed evaluation of intra-individual variability and physiological changes due to feeding. The results suggest that every subject is characterized by a typical profile that does not change with time under physiological conditions and is independent of feeding. Thus, a $^1$H-MRS urinary profile may be considered as an individual’s metabolic fingerprint. Changes in the $^1$H-MRS urinary profile of an individual may be indicative of metabolic changes or disturbances in renal function.

**Figure 6** $^1$H-NMR spectra (500 MHz) of (a) normal human urine, and urine collected from four patients 3 days following renal transplantation showing: (b) immediate functioning graft; (c) urinary tract infection; (d) renal tubular ischemia; and (e) non-functioning graft. 4 DIAGNOSIS OF NEUROLOGICAL DISORDERS

The use of high-resolution $^1$H-MRS to evaluate brain metabolism through the metabolic profile of CSF constitutes a potentially powerful strategy to aid the differential diagnosis of neurological diseases. Although the biochemical composition of CSF has been well characterized by standard biochemical techniques, a number of studies have been done to evaluate the effectiveness of $^1$H-NMR spectroscopy for examination of CSF as an aid to the biochemical diagnosis of central-nervous-system diseases. Early studies reported the assignments of a number of resonances. Since then, a number of pattern-recognition approaches and discriminant analyses have been used to separate samples into different classes, and these used to differentiate between normal controls and subjects with various neurological disorders.

Koschorek et al. reported that the spectra of CSF of normal controls and subjects with tumors or multiple sclerosis (MS) can be perfectly separated, whereas those from subjects with disk herniations can be separated approximately 90% of the time using principal component analysis (PCA).

500 MHz $^1$H-NMR spectra of postmortem CSF specimens from control subjects and patients with Alzheimer’s disease were examined in a similar study. PCA achieved partial separation of the groups; more formal statistical analysis suggested that citrate by itself was the best discriminator.

Spectra showing the metabolic brain profile induced by degenerative dementia are reported to be considerably different from those of control patients. An increase in many metabolites has been observed, and for some (leucine–isoleucine) the concentration is increased threefold. Furthermore, some abnormal and unassigned resonances have been observed. These qualitative MRS abnormalities were not found to be correlated with any medical treatments.

In the CSF of patients with Huntington’s chorea, 400 MHz $^1$H-MRS analysis demonstrated a significant increase (approximately 60%) in the pyruvate concentration as compared to controls. However, in serum samples, no variation in this metabolite was detected.

In studies of CSF from patients with MS, the findings among studies differ. Lynch et al. reported that there were no significant differences between the levels of most metabolites, with the exception of acetate and formate which were increased and decreased respectively in patients with MS as compared to controls. Moreover, in 93% of patients with actively progressing MS, an unknown singlet peak at 2.82 ppm was found; it was presumed to be an $N$-methyl compound. Nicoli et al. similarly reported that MS induced only slight modifications in the $^1$H-MRS spectra, but these modifications differ from those reported earlier: an increase in lactate and fructose, and a decrease in creatinine and phenylalanine concentrations. Further, the unknown $N$-methyl compound described previously was not found in the CSF of any of the patients with MS. Interestingly, Aasly et al. observed significantly lower levels of lactate and glutamine in MS patients as compared to controls. When the MS group was divided into two subgroups (chronic progressive and relapsing–remitting forms of MS), no significant differences were found in any of the parameters measured in the CSF, although there was a tendency toward lower levels of lactate and glutamine in the relapsing–remitting groups.

What accounts for the different results in these studies is unclear; it may simply reflect the lack of a standardized method for specimen preparation and recording $^1$H-MRS spectra from CSF. A standardized method for high-resolution $^1$H-MRS of CSF needs to be adopted.

5 CANCER DIAGNOSIS

Increased research in the field of cancer diagnosis and treatment over the past several years included a search for an inexpensive, accurate, and noninvasive screening test for early malignancy. It had been hoped that a simple screening test of plasma, using $^1$H-MRS, might reveal a malignant condition. However, these investigations have been unsuccessful, and attention has shifted toward the assessment of various tissue specimens, and extracts of tissue specimens, to determine whether $^1$H-MRS can differentiate between malignant and nonmalignant diseases.

5.1 Colon Cancer

Colon cancer was the first disease to be approached in detail by $^1$H-NMR. A large number of spectra were obtained from colon tumors, and from tissue at the surgical margins of the removed colonic region to serve as normals. A very wide variety of spectra was obtained, and the longitudinal relaxation time of the lipid resonance at 1.3 ppm in the $^1$H spectrum was used as an indicator of metastatic potential, whereas the intensities of resonances due to choline-containing compounds correlated with the degree of invasion of the cancer (Dukes A, B, C, or D). Subsequent studies on cultured human cell lines of different degrees of invasive capability showed that two-dimensional COSY $^1$H spectra could be discriminatory. Figure 7 shows the COSY spectra of these cell lines, with a cross-peak between 1.3 and 4.2 ppm whose intensity increases with the aggressivity of the cancer. It was postulated that this cross-peak is due to the sugar fucose, located in surface
Figure 7 ¹H-NMR spectrum (360 MHz) COSY spectrum (magnitude mode, symmetrized) of excised tissue in 400 µL phosphate-buffered saline in D₂O, for a specimen of human ovarian serous carcinoma, poorly differentiated. Multiple cross-peaks are attributable to cell–surface fucosylation, namely Thr/Fuc I (1.33–4.27 ppm), which also contains a contribution from the amino acid threonine, Fuc II (1.25–4.28 ppm) Fuc IIb (1.19–4.20 ppm), and Fuc III (1.41–4.30 ppm), and correlated with tumor grade and loss of cellular differentiation. (Reproduced by permission from Blandford and Smith. 8)

antigens that interfere with the normal immunochemical recognition of cancer cells.

More recent studies of colon tissue revealed another critical element – the purity of the colon tissue. If care is not taken to exclude both muscle and subepithelial fat from the specimen, resonances from these underlying tissues may confound the analysis. A definitive study was performed using well-defined specimens, and rigorous analytical methods, showing that ¹H-NMR can yield very high levels of sensitivity and specificity for the detection of cancer. (22) More recently, this approach has been applied to the evaluation of other colonic disorders, such as Crohn’s disease and inflammatory bowel disease. (68) The chemical discriminatory power of ¹H-NMR is expected to provide valuable insight into the progression of colon disease from dysplasia to malignancy, and to interpret the progression in terms of the oncogenic genes expressed during the progression.

5.2 Thyroid Cancer

A problem in thyroid cancer is the detection of follicular malignancy. Regular histopathological procedures cannot yield a conclusion. Only thyroidectomy, and analysis of the entire gland, can yield a definitive diagnosis of invasive disease. However, the patient has already lost the thyroid gland. ¹H-NMR studies on thyroid biopsies by both surgical and needle approaches demonstrated a high level of sensitivity to thyroid cancer, and provided a serious test of the multivariate methods for spectral
analysis. This approach is now used in Australia to determine the therapy applied to neoplasms of the thyroid (C.E. Mountford, personal communication).

5.3 Brain Tumors

A variety of human brain neoplasms have been studied by this technique. Figure 8 shows the $^1$H-NMR spectra of tissue from three different brain tumor types, and a patient with epilepsy. Relatively simple data analysis allowed accurate classification of these cancers, and gave cause for hope for a method to determine their degree of aggressivity. The resonance at 1.3 ppm due to lipid was seen to be indicative of the degree of necrosis (dead tissue) in the tumor. In vivo studies of brain tumors have now been reported and it is expected that $^1$H-NMR will be a valuable technique for the planning of treatment for brain tumors.

5.4 Ovarian Tumors

$^1$H-NMR spectra of ovary biopsy specimens have shown good sensitivity to the presence of malignant disease by both resonance ratio and multivariate methods. In the latter study, sensitivity of the tumor to drug therapy was also detected by the method. It is hoped that in vivo use of this method will help detect ovarian cancer at an early stage, and define its potential resistance to therapy.

5.5 Prostate Cancer

Screening of prostate tissue is currently done by transurethral or transcolonic biopsy. In both methods, the sampling is not representative of the entire gland. $^1$H-NMR of prostate tissue has demonstrated remarkable discriminatory power. Benign disease can be distinguished from cancer with sensitivity of 100%, and specificity of 95.5%. Furthermore, the method appears to be capable of distinguishing the stromal and glandular forms of benign prostatic hypertrophy (Figure 9). Recent transrectal $^1$H-NMR spectra in vivo show spectra with similar detail, which promise to yield an accurate whole-gland diagnosis.

5.6 Other Neoplastic Conditions

Studies are now under way on a variety of other tissues – cervix, esophagus, breast, kidney, and neck. Results are preliminary, but show a high degree of promise.

6 CONCLUSIONS

The range of applications of $^1$H-NMR of biological fluids is wide, and is growing steadily. The study of the composition of physiological fluids and tissues, and the changes thereof in disease, are amenable to study by MRS. Although a greater availability of instruments, standardized methodology, a larger database of spectral changes correlated with pathological conditions, and more NMR-trained individuals in the clinical environment are necessary for routine use, the discriminating power of MRS can be exploited to attack difficult clinical problems. It can be used to determine the chemical components that characterize a particular disease.

The ex vivo $^1$H-NMR of tissue technique has also enjoyed a remarkable degree of success in distinguishing cancer tissue from normal or otherwise abnormal tissue. The methods thus developed should lead to extension of the studies to human subjects in vivo with a high degree of accuracy. These future studies will be, of course, more time-consuming but it is expected that the savings in lives and treatment cost will readily justify the effort. Now is the time to proceed!

Nuclear magnetic resonance (NMR) is the basic physical phenomenon in which certain nuclei absorb and emit radiofrequency (RF) radiation while in the presence of a magnetic field. The noninvasive nature of NMR techniques, including magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS), has allowed explosive developments in biomedical applications since the late 1970s. MRI of protons is now a widely accepted clinical imaging technique, whereas MRS of various nuclei, including 31P, 1H, 13C, 23Na, and 19F, can provide a vast amount of metabolic and physiological information. MRI provides significant advantages over many other imaging techniques in terms of resolution, contrast, and its noninvasive nature. Although not as common in clinical medicine, MRS also provides valuable metabolic information that cannot be obtained by other techniques. This article reviews the fundamentals of spatial encoding, contrast, artifacts, and applications of MRI as well as some recent advances in the field. Some applications of biomedical MRS of various nuclei are also discussed.

The sections “History of Biomedical NMR” and “Overview of Instrumentation” in this article are based in part on the online book, “The Basics of MRI”, by Joseph P Hornak, http://www.cis.rit.edu/htbooks/mri/.

1 INTRODUCTION

NMR spectroscopy is widely used in chemistry to obtain detailed structural and motional information about complex molecules. Electromagnetic radiation in the frequency range of radio and television transmissions is used, often called RF radiation, which easily penetrates biological tissue without the adverse health effects of ionizing radiation, such as X-ray radiation. This unique feature has allowed explosive developments in noninvasive biomedical applications of NMR techniques since the late 1970s. MRI of protons (1H) is now a widely accepted clinical imaging technique, primarily due to its ability to image soft tissue, such as the white matter and gray matter of the brain. NMR techniques can also provide a vast amount of metabolic and physiological information by observing 1H and other nuclei in the tissue.

This article presents a concise introduction to the field of MRI including the history, instrumentation, advantages, and disadvantages of MRI technologies. The fundamentals of spatial encoding, contrast, artifacts and applications of MRI are reviewed, as well as some recent advances in the field. Also discussed is MRS of various nuclei, including 31P, 1H, 13C, 23Na, and 19F. The intention is to cover the major topics in biomedical NMR and describe the general techniques and applications of MRI and MRS. The related articles listed at the end of this chapter provide more detailed descriptions of specific topics.

1.1 History of Biomedical Nuclear Magnetic Resonance

Bloch and Purcell, both of whom were awarded the Nobel Prize in 1952, discovered the magnetic resonance
phenomenon in 1946.\textsuperscript{1,2} In the period between 1950 and 1970, NMR techniques were developed and used for chemical and physical molecular analysis. In 1973, Lauterbur proposed that NMR could be exploited to image the human body by the back-projection technique used in computed tomography (CT).\textsuperscript{3} In 1975, Ernst proposed MRI using phase and frequency encoding, the current MRI technique.\textsuperscript{4} Edelstein et al. demonstrated the feasibility of imaging the body using this technique in 1980.\textsuperscript{5} A single image could be acquired in approximately 5 min. During the same time period, the first localized NMR spectra from living animals were obtained.\textsuperscript{6–9} By 1996, the image acquisition time had been reduced to a matter of seconds, without sacrificing too much image quality. In 1989, Dumoulin et al. perfected magnetic resonance angiography, allowing flowing blood to be imaged without the use of contrast agents.\textsuperscript{10} In 1989, echo-planar imaging (EPI) was introduced which permitted image acquisition at video rates (30 ms).\textsuperscript{11} The EPI method has enabled the technique now referred to as functional brain imaging, which allows the regions of the brain responsible for thought and motor control to be mapped. In 1991, Richard Ernst was awarded the Nobel Prize in Chemistry for his achievements in pulsed NMR and MRI. Biomedical NMR is clearly a young, but growing, science.

1.2 Overview of Instrumentation

A magnetic resonance system used for clinical applications consists of several hardware components working together to form the desired images. The most noticeable component is the magnet (Figure 1), which houses the shim coils, gradient coils and RF coils. Additional hardware includes gradient amplifiers, RF transmitting and receiving electronics, and a host computer for integration and interfacing all the hardware and software components. A simple diagram of the major components of a magnetic resonance imager and a few of the major interconnections are shown in Figure 2. At the top are the components located in the scan room of a magnetic resonance imager. The magnet produces a large static magnetic field, denoted by $B_0$, for the imaging procedure. Within the bore of the magnet, the gradient coils produce spatial magnetic field gradients in $B_0$ along the $x$, $y$, and $z$ directions. Within the gradient coils is the RF coil, which produces an oscillating magnetic field perpendicular to $B_0$, denoted $B_1$. The $B_1$ field is necessary to rotate the nuclear spins in the body, often by 90° or 180°. The RF coil is also used to detect the signal from the spins within the body. The patient is positioned within the magnet by a computer-controlled table. This table has a positioning accuracy of 1 mm. The scan room itself is RF shielded, usually by copper sheets within the walls to prevent RF emission as well as interference from outside RF signals. A magnetic shield made of thick steel plates also surrounds most scan rooms. This shield restricts the magnetic field from extending out of the scanner room. Self-shielded magnets are also now available, eliminating the need for large steel structures.

The computer on a magnetic resonance system controls all components of the imager. The RF components under computer control are the RF source and pulse programmer. The source produces a sine wave of the desired frequency. The pulse programmer shapes the

RF pulses into the desired form, usually an apodized SINC pulse (i.e. following the mathematical function $\text{SINC}(t) = \sin(t)/t$ with $t$ representing the variable time). The RF amplifier increases the pulse power from milliwatts to kilowatts. The computer also controls the gradient pulse programmer, which sets the shape and amplitude of each of the three gradient fields. The gradient amplifier increases the power of the gradient pulses to a level sufficient to drive the gradient coils. Some imagers also have an array processor, a device that is capable of performing a two-dimensional (2-D) Fourier transform in fractions of a second. The computer off-loads the Fourier transform to this faster device.

The operator of the imager gives input to the computer through a control console. An imaging sequence is selected and customized from the console. The operator can see the images on a video display located on the console or can make hard copies of the images on a film printer.

Further details about the magnet, shim coils, gradient coils, and RF coils on a magnetic resonance imager are discussed below.

### 1.2.1 Magnet

The magnets used for medical applications have an inside diameter of about 1 m and a horizontal orientation to facilitate moving the patient in and out of the magnet bore. Three types of magnets have been used in MRI, permanent, resistive and superconducting.

Permanent magnets are constructed of permanently magnetized ferromagnetic materials. They are least expensive and have low maintenance costs because they do not require electrical power or expensive cryogens. Permanent magnets can be designed with three open sides, a configuration known as open MRI. This allows greater access and visibility for patients. Permanent magnets, however, are extremely heavy, weighing up to 100 tons and are limited to field strengths around 0.35 T or less. They tend to produce low-quality images and are usually not adequate for spectroscopic applications because of the relatively weak and inhomogeneous magnetic field. The low magnetic field strength makes a permanent magnet less hazardous to patients and staff but, if an accident occurs, a permanent magnet cannot be turned off. A further discussion of the safety issues associated with MRI equipment can be found in section 2.5.

Resistive electromagnets produce a magnetic field by running electrical current through a coil of wire. The magnetic field is oriented perpendicular to the plane of the coil. The power consumption required to achieve the necessary field strengths (~0.3 T) is similar to that of a large office building. This produces a lot of heat, necessitating a cooling system to protect the patient and the magnet coils. A resistive electromagnet can be turned off when not in use or during an emergency. The high cost of the electricity and water cooling system required to operate a resistive electromagnet has prevented its widespread use in MRI.

Superconducting magnets work on the same principal as electromagnets. However, the coil windings are made of superconducting wire, often alloys of niobium and tin, that loses its electrical resistance as the temperature approaches absolute zero, $-273 ^\circ \text{C}$. With no resistance, no energy is lost as current runs through the wire. Therefore, no energy is required to keep the magnet running once the coil has been energized and superconducting magnets do not accrue the high-energy costs of resistive magnets. Although no heat is generated as current runs through the wire, a cryogen cooling system is required to keep the coil near absolute zero. This is achieved by immersing the coil in a bath of liquid helium. The helium chamber is surrounded by vacuum chambers and a liquid nitrogen chamber to reduce evaporation of the liquid helium. In superconducting magnets, replenishing the evaporated cryogens represents the predominate operating cost. Most MRI scanners use a superconducting magnet because they can produce a very strong and uniform magnetic field over a large area. The maximum field strength currently used in clinical imaging is 1.5 T, whereas experimental scanners may exceed 4 T. A superconducting magnet is typically not shut down when not in use and will remain active even during power failures. However, they can quickly be turned off in case of an emergency. This requires specific safety precautions and specialized training of the MRI staff.

### 1.2.2 Shim Coils

The shim coils are used to optimize the magnetic field homogeneity over the imaging volume. The field may change over time, when a patient enters the magnet or due to changes in position of metallic objects near the scanner room. A magnetic field inhomogeneity of just a few parts per million (ppm) leads to noticeable shading of magnetic resonance images, whereas greater inhomogeneities give rise to spatial distortions in the images. In general, NMR spectroscopy requires even better field homogeneity than does imaging. As many as 30 different shim coils may be used to adjust the field strength by carefully adjusting the amount of current in each coil until acceptable homogeneity is achieved.
1.2.3 Gradient Coils

Gradient coils are used to encode spatial information in the NMR signal during imaging and certain spectroscopy examinations. The coils are arranged along the three orthogonal axes so that the magnetic field can be manipulated in each direction. Gradients along other oblique axes can be implemented with combinations of the orthogonal gradients.\textsuperscript{16} Figure 3 shows the basic gradient coil design for obtaining the three orthogonal gradients. The gradient along the axis of the magnet (z direction) is achieved with a pair of circular coils, shown in Figure 3(b). The currents in the two coils flow in opposite directions creating a magnetic field gradient between them. The magnetic field of one coil adds to the main magnetic field while the field from the other coil subtracts from the main magnetic field. The x and y gradients are created by a pair of figure-of-eight coils, shown in Figure 3(c) and 3(d), respectively. Power is supplied to each of the gradient coils by independent computer-controlled gradient amplifiers. The gradient coils are positioned in the magnet such that the mid-point of each set is at the center of the magnet, denoted as the isocenter. Thus, the magnetic field is not changed at the isocenter when the gradients are switched on and off.

The four most important properties of a gradient system are: (a) the attainable gradient amplitude, (b) gradient linearity, (c) gradient rise time, and (d) eddy currents generated by the gradients. The maximum attainable gradient amplitude (the change in magnetic field per unit distance, often cited in units of gauss cm\textsuperscript{−1}) limits the minimum slice thickness and minimum field of view (FOV) that can be used. Gradient linearity refers to the uniformity of the slope along the gradient axis; nonlinearity yields image distortions. How fast a gradient can be powered from zero to full amplitude is referred to as the rise time, which should be as short as possible. The act of switching gradients on and off induces the formation of undesirable eddy currents in the metallic structures of the magnet. These eddy currents generate magnetic fields of their own, which dissipate at differing rates and can have deleterious effects on image quality. This problem can be overcome by driving the gradient coils with an empirically determined pulse shape, which cancels out eddy current contributions. A potentially more powerful approach is the use of self-shielded gradient coils. These coils are constructed such that the generated magnetic fields are confined to the interior of the coils, thus preventing the formation of eddy currents in the remainder of the magnet.

1.2.4 Radiofrequency CoilsRF

A coil is also needed for transmission of RF radiation to excite the nuclei and to receive the emitted RF energy. As a basic analogy, the RF coil acts like an antenna. The design of coils can vary in size, shape, orientation and characteristics to suit their particular application. Two separate coils may be used for transmission and reception, or a single coil can serve both purposes. To illustrate the dual role of these coils, they are often called transceiver coils.

The RF coil has to be tuned and matched to maximize the efficiency. Like any antenna, the coil is tuned to maximize the sensitivity at the desired frequency and reduce the sensitivity to other frequencies. During excitation, this lowers the power requirements and minimizes patient exposure to unnecessary RF fields. This also maximizes the acquired signal while cutting down on the noise picked up by the coil. In addition, basic RF theory dictates that the maximum power is emitted from an antenna when the impedance of the antenna is matched to the rest of the electronics, typically 50\,Ω. Tuning and matching the RF coil optimizes the performance of the MRI scanner producing the highest possible quality of images.

A circuit diagram of a simple coil is shown in Figure 4. The coil of wire is modeled as an inductor, labeled L in the circuit diagram. The capacitor \( C_t \) is used to tune the circuit, and the series capacitor \( C_m \) matches the circuit to 50\,Ω.

The most basic coil, called a surface coil, is a simple loop of wire.\textsuperscript{17} Figure 5 is a photograph of a variety of surface coils. They are very easy to build and can be placed directly over the sample for maximum sensitivity. However, the coil does not produce a uniform magnetic field. Only signals very close to the coil itself can be
Circuit diagram of a simple RF coil. Capacitor $C_t$ is used to tune the coil to the resonant frequency, and $C_m$ matches the coil to the characteristic impedance of the RF electronics, typically 50 $\Omega$.

Figure 4

Photograph of a variety of surface coils. Different sizes and shapes are used to image different parts of the body. The conductive loop is contained in a rigid plastic housing and the cables connect the coil to the RF electronics in the MRI scanner magnet. (Photo courtesy of Philips Medical Systems, Inc.).

Figure 5

excited and received. Therefore, surface coils are often used to receive signals from a localized area of the body. The coil must be positioned such that the magnetic field created by the coil is at right angles to the main external magnetic field. This makes the placement of a surface coil crucial to optimize the performance.

An advanced surface coil design is known as a phased-array coil. Numerous surface coils can be aligned to produce better field homogeneity along the plane of the structure. The coils can be controlled by switching circuitry or by altering the phase characteristics of each element. This reduces the noise contribution of each coil and significantly increases the available signal-to-noise ratio (SNR).

To image the body uniformly, many coil designs have been developed to produce a homogeneous magnetic field within a specified volume. An extension of the surface coil, seen in Figure 6(a), uses a series of loops to produce a uniform field oriented along its axis. This design, called a solenoid coil, maximizes both homogeneity and sensitivity and is relatively easy to construct. As the coil’s magnetic field must be perpendicular to the main magnetic field, the axis of the solenoid coil must be perpendicular to the axis of the magnet. This orientation restricts access to the coil center, making it difficult to image large objects. In addition, the solenoid coil is not suited for high-frequency applications due to self-resonance problems.

The loop gap resonator and the Helmholtz coil have been designed to overcome some of the limitations of the solenoid coil. The loop gap resonator, shown in Figure 6(b), consists of a conductive metal sheet wrapped in a cylindrical shape. The slight gap between the edges of the sheet forms an effective capacitance. This coil can be tuned to higher frequencies than a solenoid coil. However, the geometry of a loop gap resonator prohibits access to the interior of the coil once it is placed in the bore of the magnet. Figure 6(c) shows a two-turn solenoid design called a Helmholtz coil. This coil allows samples to extend beyond the coil and provides easier access to the coil center, but suffers from relatively low sensitivity and homogeneity. Both loop gap resonators and Helmholtz coils also produce a magnetic field along
their axes, requiring the coil to be oriented perpendicular to the axis of the magnet. This makes solenoid, loop gap, and Helmholtz coils inappropriate for most whole-body imaging applications on superconducting magnets.

Several coil designs produce magnetic fields perpendicular to their axes. These coils can be oriented along the magnet’s axis and still produce a perpendicular magnetic field. The saddle-shaped coil shown in Figure 6(d) produces a perpendicular magnetic field, allowing easy access to both ends of the coil. Another design is the slotted tube resonator shown in Figure 6(e). This design produces a more homogeneous magnetic field than is possible with a saddle-shaped coil. The birdcage coil seen in Figure 6(f) represents a highly advanced design. This coil offers the maximum homogeneity, sensitivity and accessibility to the coil center, allowing it to become one of the most popular designs in clinical MRI. However, a birdcage coil can be very difficult to design and construct.

An improvement in sensitivity by a factor of \(\sqrt{2}\) can be accomplished by quadrature detection. This requires that two RF coils in an orthogonal orientation be used for transmitting and receiving. If the coils are driven by RF pulses with a 90° phase shift, a rotating RF field will be produced rather than a field aligned along a single axis. The improved sensitivity can be very useful for large whole-body coils that are not close to the tissue under examination. The symmetry of the birdcage coil makes it perfectly suited for quadrature design.

There are often times when two nuclei need to be studied in biological examinations. The ability to tune a coil to more than one frequency allows examination of two nuclei in the exact same tissue under the exact same physiological states. This eliminates the need to move the patient or change the coil, reducing the time required for the examination. A simple way to construct a dual-tuned coil is shown in Figure 7. This is equivalent to the single tuned circuit with the addition of a trap circuit in series with the tuning capacitor. At the lower frequency the trap circuit is inductive, whereas the trap is capacitive at the higher frequency. The series combination of the tuning capacitor and the inductive trap at the lower frequency tunes the circuit to the lower frequency. Likewise, the combination of the tuning and trap capacitors when driven by high frequency tunes the circuit to the higher frequency. Using similar design strategies, more trap circuits can be added to create triple, quadruple, or higher-tuned coils.

1.3 Advantages

MRI has many advantages over other clinical imaging techniques and may be preferable to many chemical analysis techniques. Unlike many other imaging methods, MRI does not use ionizing radiation. X-ray and CT image the human body by recording the density of various structures. The denser materials, such as bone, absorb more radiation than the soft tissues. Single photon emission computed tomography (SPECT) and positron emission tomography (PET) are two other imaging methods that employ ionizing radiation in a very different way. These techniques follow radioactively labeled metabolites through the body. The resolution and SNR available with methods using ionizing radiation are often limited by the acceptable dose of radiation. In addition, cumulative exposure to radiation limits the number of times a patient can be imaged using these techniques. As MRI does not require the use of radioactive materials, the resolution and SNR do not suffer from the same restraints, and MRI can be used repeatedly without concern for cumulative radiation exposure.

Another strength of MRI is its high temporal and spatial resolution. Modern MRI techniques allow images to be collected within tens of milliseconds with resolutions of the order of millimeters. These feats cannot be achieved with classical radiographic methods. Other noninvasive techniques, such as ultrasound and optical imaging, also suffer from poor spatial resolution.

The contrast obtained from most imaging methods, including X-ray, CT, SPECT, PET, and ultrasound, depends upon the density of tissue or an exogenous contrast agent. However, MRI is much more versatile and can use the physical properties of tissue, such as density or relaxation, or specially designed contrast agents, such as relaxation agents. In addition, MRI can exploit numerous other forms of contrast, such as flowing blood, diffusive movement, or changes in blood oxygen saturation. This allows MRI to be employed in a wide variety of imaging applications.
The MRI technique has proved useful in the detection of many different types of brain diseases and disorders. It is often the preferred method clinically to diagnose and characterize brain tumors, infections, cerebrovascular disease, head trauma, intracranial hemorrhage, and white-matter disease. It can detect a wide variety of diseases including multiple sclerosis, herpes simplex virus type 1, meningitis, stroke and AIDS.

MRI has gained widespread acceptance as an invaluable diagnostic tool in many other parts of the body, including the cardiac, musculoskeletal, and abdominal systems. The soft-tissue contrast abilities, multiplanar imaging and large FOV, has made MRI a valuable tool for evaluating gynecological diseases. For example, MRI is 77–100% more sensitive in the detection of müllerian duct anomalies than classical ultrasound.26–28 and has an accuracy greater than 90% for differentiating and staging various types of uterine tumors.29–36 Clinical trials are currently evaluating three liver-specific MRI contrast agents: manganese $N,N'$-bis(pyridoxal-5-phosphate)ethylenediamine-$N,N'$-diacetic acid (Mn-DPDP), gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid (Gd-EOB-DTPA) and gadolinium benzyl oxypropionictetraacetate dimeglumine (Gd-BOPTA-Dimeg).37–42 These agents are preferentially taken up by hepatocytes within 30–120 min after intravenous injection and then cleared by the bile and renal systems. The rate of contrast uptake and the enhancement patterns can be used to characterize liver lesions.

NMR spectroscopy can be used to determine the chemical properties of tissues. It can detect which chemical species are present, how the body metabolizes various drugs, and how physiological perturbations alter tissue function. Unlike other analytical chemistry tools with biomedical applications, such as mass spectroscopy and atomic absorption, NMR does not require removal and destruction of the sample. Hence, NMR does not alter the tissue characteristics and allows repeated measurements from the same tissue. Similarly, some clinical methods, such as biopsy and histology, require invasive and potentially harmful techniques. Repeated measurements on the same sample cannot be performed with mass spectroscopy, atomic absorption, or histology. However, NMR can be performed noninvasively and serially on the same tissue.

1.4 Disadvantages

In the clinical setting MRI also has several disadvantages. The first is the complex and expensive instrumentation required to implement MRI. This equipment needs constant maintenance and care. The magnet, in particular, requires regular maintenance to replace the liquid helium and nitrogen that cools the superconducting coils. The equipment is so bulky that the patient must be transported to the imager. For some critical care patients this may be impossible. The stray magnetic fields and heavy magnets also require special housing considerations for a MRI scanner.

From a chemical analysis perspective, NMR has certain disadvantages compared to other methods. The sensitivity of NMR is much lower than found in mass spectroscopy and atomic absorption techniques. In addition, NMR may require complicated calibration routines if quantitative results are needed.

Although MRI uses only RF radiation, some people are not suited for imaging. People with pace makers, metallic implants or metallic prostheses are not imaged because of the dangers related to strong magnetic fields. In addition, caution must be exercised in MRI examination of patients who are pregnant. As with all interventions in pregnancy, MRI should be used during the first trimester when it offers a definite advantage over other tests.

2 PROTON IMAGING

2.1 Spatial Encoding and Imaging Pulse Sequences

To produce an image of the human body, the magnetic resonance signal must be spatially encoded along three orthogonal axes. Magnetic field gradients are used to alter the frequency or phase of the magnetic resonance signal based upon its spatial origin. Thus, gradients allow the magnetic resonance data to be reconstructed into an image of the patient. While a magnetic field gradient is on, the resonant frequency of the nuclei will change according to position along the gradient axis. A stronger gradient will cause a larger change in the resonant frequencies. When the gradient is turned off, the spins return to the same frequency, but the phases are proportional to the position along the gradient axis. The strength and the duration of the magnetic field gradient determine the phase shift of the spins. In this way, spins “remember” that a gradient has been applied after it is turned off.

To demonstrate how the magnetic resonance signal is encoded in three dimensions, assume that the patient is lying on his back in the magnet, as shown in Figure 2. The coordinate system is defined such that the $z$ axis is along the axis of the magnet, the $x$ axis is up and down, and the $y$ axis is left to right. It is assumed that images of axial slices through the patient are being collected. Therefore, slice selection will be along the $z$ axis, frequency encoding will be along the $x$ axis, and phase encoding will be along the $y$ axis. These methods are easily modified to obtain sagittal (slice selection along the $y$ axis, frequency encoding along the $z$ axis) or coronal (slice selection along the $x$ axis, frequency encoding along the $y$ axis).
encoding along the \( z \) axis and phase encoding along the \( x \) axis) or coronal slices (slice selection along the \( x \) axis, frequency encoding along the \( z \) axis and phase encoding along the \( y \) axis). Figure 8 shows diagrams of the three most common medical imaging planes. In addition, these methods can be generalized to image any arbitrary plane, as described in the oblique imaging section.

The basic pulse sequence used in MRI is the spin–echo sequence shown in Figure 9. A spin–echo sequence uses a 90° RF pulse to excite the nuclei and a 180° pulse to refocus inhomogeneities in the main magnetic field. In addition, the delay between the 90° and 180° pulses allows for spatial encoding of the magnetic resonance signal. The time between the 90° pulse and the formation of the echo is equal to the echo time (TE). The time between the 90° and 180° pulses is equal to TE/2. The time between the start of the last sequence and the start of the next sequence is the repetition time (TR). To encode the magnetic resonance signal in all three dimensions, three spatial encoding techniques are required: slice selection, frequency encoding, and phase encoding.

2.1.1 Slice Selection
Swell selection is used to excite and receive signals from only a single thin plane along the \( z \) axis. This spatially encodes the signal in the first dimension. Slice selection requires the application of a magnetic field gradient along the \( z \) axis. This gradient alters the resonance frequency for nuclei at different positions along the \( z \) axis. An RF pulse can be applied that only excites a limited band of these resonance frequencies. Application of both a magnetic field gradient and a RF pulse with a narrow bandwidth will excite only those nuclei in the \( x \)–\( y \) plane, matching the RF with the resonance frequency. Typically, the amplitude of the frequency-selective RF pulse has a SINC shape, causing the selected slice to have a rectangular profile. Other pulse shapes have also been used to obtain a uniform slice excitation. The position of the slice can be altered by changing the frequency of the band-limited RF pulse. The thickness of the slice can be changed by modifying the bandwidth of the RF pulse or by changing the magnitude of the gradient.

In Figure 9, both the 90° and 180° pulses are slice-selective pulses. In addition, the negative lobe on the \( z \) gradient is used to correct for the dephasing caused by the 90° slice-selective gradient. No rephasing is required after the 180° pulse because the 180° pulse causes the first half of the gradient to balance with the second half.

2.1.2 Frequency Encoding
The \( x \) dimension is encoded using a magnetic field gradient applied during data collection, called the readout gradient. During data collection, all of the excited spins are emitting RF energy at a frequency proportional to the magnetic field. By applying a gradient along the \( x \) axis, the frequency of the magnetic resonance signal is proportional to the position along the \( x \) dimension. The gradient along the \( x \) axis in Figure 9 prior to application of the 180° pulse is to correct for dephasing caused by the readout gradient. These two gradients ensure that the net phase at the center of the readout gradient will be zero. Alternatively, the dephasing gradient may be placed after the 180° pulse, but the magnitude must be reversed to cancel the readout gradient.

2.1.3 Phase Encoding
Spatial encoding along the \( y \) axis requires phase encoding. In Figure 9, the phase-encoding gradient is applied along the \( y \) axis between the 90° and 180° pulses. This gradient has no effect on the frequency of the acquired signal. Instead, the gradient imparts a phase that is proportional to the position along the \( y \) axis. In order
to generate a unique combination of phase and frequency for each pixel in the image plane, the imaging sequence is repeated several times with different phase-encoding gradient amplitudes.

2.1.4 k-Space Representation of Magnetic Resonance Data

The readout and phase-encoding magnetic resonance data is collected in a conceptual matrix known as k-space. The horizontal axis of k-space corresponds to the phase axis and the vertical axis corresponds to the frequency axis. The number of horizontal lines in k-space is equal to the number of phase-encoding steps and the number of points in each horizontal line is equal to the number of data points collected for each echo. In a spin–echo pulse sequence, one line of k-space is filled for each echo acquisition. The central horizontal line is collected when no phase-encoding gradient is applied. Positive phase-encoding gradients fill the upper half of k-space and negative phase-encoding gradients fill the lower half. As the phase-encoding gradients become stronger (in either the positive or negative direction) k-space lines further away from the center line are filled (top or bottom, respectively). Because a stronger phase-encoding gradient causes more dephasing, the top and bottom lines of k-space have less signal intensity than the middle lines. Similarly, the central portion of an echo has higher amplitude than the outer portion. Therefore, most of the magnetic resonance signal is concentrated around the center (both in the horizontal and vertical dimensions) of k-space.

It is important to remember that k-space does not correspond to the magnetic resonance image, that is, the top line of k-space is not the top line of the image. The central portion of k-space (with the highest signal) provides low-resolution information that corresponds to large areas of uniform signal intensity in the image. In comparison, the outer portions of k-space (with relatively little signal) provide high-resolution information that details fine aspects and borders of different objects in the image.

A spin–echo pulse sequence fills one line of k-space with every acquisition. Other pulse sequences may fill k-space in other ways. For instance, echo planar imaging pulse sequences fill all lines of k-space with a single acquisition. Typically, k-space is filled in a rectangular pattern, but some pulse sequences use spiral or radial patterns (which then must be interpolated onto the rectangular data points for discrete Fourier transformation). The data is stored in k-space and multidimensional Fourier transformations, as described in the next section, are performed to reconstruct the magnetic resonance images.

2.1.5 Image Reconstruction

The process of magnetic resonance image reconstruction is summarized in Figure 10. MRI produces a set of echo signals from each slice. Fourier transformation of each echo reconstructs the image information along the $x$ axis. This process reveals the spatial information contained in the frequency content of the signal. To recover the

![Figure 10](image)
phase-encoded information, a second Fourier transform must be performed in the second dimension. This reveals the spatial information contained in the phase content of the signal. This 2-D Fourier transformation produces the image through a slice in the patient.

2.1.6 Multislice Imaging

If one needs to obtain images from multiple slices, one could repeat the above 2-D imaging experiment several times and obtain multiple images. However, this would increase the image data collection time substantially. Another approach is to excite and detect a different parallel slice during the TR time when one is waiting for $T_1$ processes to restore longitudinal magnetization in the first slice. The only restriction is that the excitation used for one slice must not affect those from another slice. This can be accomplished by applying one magnitude slice selection gradient and changing the RF. In fact, excitation/detection may be carried out in many parallel slices during each TR interval and images from multiple slices can be collected without increasing the total data collection time.

2.1.7 Oblique Imaging

Oblique imaging is the production of images that lie between the conventional $x$, $y$, and $z$ axes. Oblique imaging is performed by applying linear combinations of the $x$, $y$, and $z$ magnetic field gradients so as to produce a slice-selection gradient perpendicular to the imaged plane, a phase-encoding gradient along one edge of the imaged plane, and a frequency-encoding gradient along the remaining edge of the image. For example, Figure 11 shows an image slice lying along the $x$ axis but passing between the $z$ and $y$ axes such that it makes a 30° angle with respect to the $y$ axis and a 60° angle with the $z$ axis. The following combination of gradients will be needed to image this slice: slice-selection gradient, $G_z = G_s \sin 60°$ and $G_y = -G_s \cos 60°$; phase-encoding gradient; $G_x = G_p \sin 30°$ and $G_y = G_p \cos 30°$; frequency-encoding gradient, $G_z$. In a similar fashion, double-oblique imaging is often employed in cardiac imaging to obtain long-axis or short-axis views of the heart.

2.1.8 Volume Imaging

The essential idea in volume imaging, or three-dimensional (3-D) imaging, is the replacement of slice-selective excitation with another phase-encoding process along the slice axis. A 3-D imaging pulse sequence is shown in Figure 12. Each RF pulse excites the entire imaging volume instead of just one slice. This is followed by two phase-encoding gradients and one frequency-encoding gradient. A 3-D Fourier transformation of the data set yields a 3-D image, which may be arranged to yield sets of axial, sagittal, coronal, or oblique images.

In practice, it is often desirable to limit the 3-D acquisition to just a portion of the sensitive volume within the RF coil. This is accomplished by selecting a slab encompassing the slices to be imaged. The 3-D acquisition then results in subdividing the slab into thinner slices. The main drawback of 3-D imaging is long data collection time. However, in some instances when a short TR is used, 3-D imaging may produce better SNR compared to multislice 2-D imaging.

2.2 Relaxation and Image Contrast

As stated earlier, RF radiation at the resonance frequency excites the nuclei during a MRI examination. Relaxation of the nuclei is governed by two mechanisms, longitudinal and transverse relaxation. These relaxation effects are commonly used to generate contrast in magnetic resonance images.
2.2.1 Longitudinal Relaxation

The mechanism by which spins relax back to equilibrium is called longitudinal relaxation or spin–lattice relaxation. Longitudinal relaxation describes the process of nuclei returning to the lower energy state by losing energy to their surroundings. This process is also called spin–lattice relaxation to emphasize the exchange of energy between the excited spins and their surroundings. The return of spins to the lower energy state is an exponential process, given by Equation (1):

$$M_z = M_0^z (1 - e^{-t/T_1})$$

where $M_0^z$ is the net equilibrium magnetization, $M_z$ is the longitudinal magnetization at time $t$, and $T_1$ is the time constant for longitudinal relaxation. Spins are considered completely relaxed after 3–5 $T_1$ times.

2.2.2 Transverse Relaxation

Transverse relaxation, also called spin–spin relaxation, occurs when spins in the high and low energy state exchange energy but do not lose energy to the surrounding lattice. This results in loss of magnetization in the transverse plane. The rate of loss of transverse magnetization is also an exponential process given by Equation (2):

$$M_{xy} = M_{0xy} e^{-t/T_2}$$

where $M_{0xy}$ is the initial transverse magnetization, $M_{xy}$ is the transverse magnetization at time $t$, and $T_2$ is the time constant for transverse relaxation.

In addition to the molecular interactions, inhomogeneities in the main magnetic field also contribute to the decay of transverse magnetization. The time constant for the combination of these two factors is called $T_2^*$ and is given by Equation (3):

$$\frac{1}{T_2^*} = \frac{1}{T_2} + \frac{1}{T_{2 inhomo}}$$

2.2.3 Factors Influencing Relaxation

The $T_1$ relaxation is short when the motion of the nucleus (rotations and translations, or tumbling rate) matches that of the resonant frequency. As a result, $T_1$ relaxation is dependent on the main magnetic field strength, which specifies the resonant frequency. Higher magnetic fields are associated with longer $T_1$ times. $T_2$ is mostly field independent for the range of magnetic field strengths used in clinical magnetic resonance. When the motion of the nucleus is fast, the $T_2$ and $T_1$ times are approximately the same. The $T_2$ becomes considerably shorter than the $T_1$ as the motion of the nuclei become slow. The $T_2^*$ time is always less than or equal to the $T_2$ time. The values of $T_1$ and $T_2$ at 1.5 T for some tissues in the human head are listed in Table 1.

2.2.4 Proton Density Weighted Images

Proton density images reflect the number of mobile hydrogen nuclei in the tissue. A spin–echo sequence with a long TR and a short TE will produce a proton density weighted image. The long TR allows all the spins to return to their relaxed state before the start of the next sequence. In addition, the short TE minimizes the effects of $T_2$ relaxation. Owing to the long TR required, the imaging time for proton density images can be very long. They also suffer from poor contrast because most tissues have essentially the same concentration of protons. A typical proton density image of the brain is shown in Figure 13. This image was collected with a TR of 6s and a TE of 20ms.

2.2.5 $T_1$-weighted Images

The contrast in $T_1$-weighted images is obtained through differences in $T_1$ relaxation times between various tissues. $T_1$-weighted images can be produced with a spin–echo

CSF, cerebrospinal fluid.

Figure 13 Examples of axial images through the brain, illustrating ventricles, gray matter and white matter. The proton density image was collected with TR/TE = 6000/20. For the $T_1$-weighted image TR/TE = 400/20; for the $T_2$-weighted image TR/TE = 4000/80. (Images courtesy of General Electric Medical Systems.).
sequence with a short TR and short TE. The short TE minimizes the effects of variations in $T_2$ values from different tissues. However, the short TR accentuates the effects of different $T_1$ values. Tissues with short $T_1$ times can fully relax back to equilibrium within the short TR time and appear bright on the final image. Tissues with long $T_1$ values cannot fully relax before the next acquisition and appear dark. A sample $T_1$-weighted image of the brain (with a TR of 400 ms and a TE of 20 ms) is shown in Figure 13. In such an image, fat is bright, CSF is dark and the gray matter of the brain is slightly darker than the white matter.

Other methods have been developed to produce $T_1$-weighted images under special circumstances. For instance, the inversion recovery sequence shown in Figure 14 enhances $T_1$ contrast and more clearly delineates gray and white matter. The inversion recovery sequence consists of a 180° pulse, which inverts the spins along the $-z$ direction, followed by an inversion recovery delay in front of the standard spin–echo pulse sequence. At a given inversion recovery delay value, the signal intensities of white and gray matter are more widely separated than in a $T_1$-weighted image obtained using a spin–echo pulse sequence. A sequence known as magnetization prepared rapid gradient echo imaging (MP/RAGE), has been developed to obtain 3-D images with high $T_1$ contrast with a very short acquisition time.

2.2.6 $T_2$-weighted Images

Another way to increase MRI contrast is to produce a $T_2$-weighted image. $T_2$-weighted images are created when both the TR and TE times are long. As with proton density images, the long TR allows all the spins to relax back to equilibrium before the next imaging cycle, minimizing $T_1$ relaxation effects. However, the long TE time allows distinction to be made between tissues with different $T_2$ times. Tissues with a short $T_2$ will lose a great deal of signal during TE and will appear dark. However, tissues with a long $T_2$ will not relax as much during TE and will appear bright. A $T_2$-weighted image of the brain is shown in Figure 13. This image was collected with a TR of 4 s and a TE of 80 ms.

Like proton density images, the spin–echo $T_2$-weighted imaging sequence uses a long TR time. Thus, the acquisition time for $T_2$-weighted images can be very long. Sometimes the proton density sequence and the $T_2$-weighted sequence are combined to reduce the total examination time. In such a sequence, the TR time is kept long but two echoes are formed. The first echo is formed with a short TE and corresponds to the proton density image. The second echo is formed after a longer TE and corresponds to the $T_2$-weighted image.

As mentioned earlier, $T_2^*$ is much shorter than $T_2$ and can obscure the action of spin–spin relaxation. The value of $T_2^*$ is a function of local inhomogeneities in the main magnetic field. To obtain an image with $T_2$ weighting, the $T_2^*$ effects must be removed from the image. The 180° pulse in a spin–echo sequence refocuses the phase shifts caused by inhomogeneities in the magnetic field, minimizing $T_2^*$ weighting.

Under certain circumstances, a spin–echo pulse sequence is not suitable. For instance, a surface coil may not be able to produce a 180° pulse due to the $B_1$ field inhomogeneities. Gradient-echo pulse sequences, such as the gradient-recalled acquisition at steady state (GRASS) pulse sequence shown in Figure 15, can create an echo signal without a RF refocusing pulse. The echo is formed by the joint action of the negative gradient and the read-out gradient along the frequency encoding axis. The negative gradient dephases the NMR signal, allowing the read-out gradient to rephase the signal and form an echo. If the negative gradient is equal to half the read-out gradient, the echo will be rephased at the center of the data collection window. The dephasing gradient can be either half the amplitude or half the duration of the read-out gradient to satisfy this condition.

Typically, a gradient echo can be formed with a shorter TE, 5–10 ms, than is possible with a spin–echo. Therefore, gradient echoes are often employed with fast imaging

![Figure 14](image1.png)  
**Figure 14** Pulse sequence for inversion recovery imaging. The first 180° pulse accentuates differences in $T_1$ relaxation. The inversion time (TI) controls the amount of $T_1$ weighting.

![Figure 15](image2.png)  
**Figure 15** GRASS pulse sequence. This sequence uses a gradient echo instead the spin–echo of Figure 9. This sequence can produce TEs of <10 ms and produces $T_2^*$-weighted images.
pulse sequences. The \( B_0 \) field inhomogeneities are not refocused due to the lack of a 180° pulse, causing gradient echo images to be \( T_2^* \) weighted. Although this is typically an unwelcome consequence, certain imaging sequences, such as the blood oxygen level dependent (BOLD) effect, rely upon \( T_2^* \) weighting to provide the desired contrast. A further discussion of functional brain imaging using the BOLD effect is presented in section 2.4.2.

2.2.7 Contrast Agents

As with conventional CT imaging, intravenous contrast agents are often used in MRI. The most common contrast agent used in MRI is gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA).\(^{47–51}\) This agent decreases the relaxation times of nearby hydrogen nuclei. In proton density images, the contrast agent does not significantly alter the image. In \( T_1 \)-weighted images, the \( T_1 \) is reduced and tissues exposed to the contrast agent appear brighter. In \( T_2^* \)-weighted images, the contrast agent decreases the \( T_2^* \) of tissues containing contrast agent and so they appear darker. The additional contrast may be used to detect hemorrhage, disruption of the blood–brain barrier, or the increased vascularity associated with tumors. Because of the highly efficient relaxation mechanisms, the dose of contrast agent required for MRI is only about 1/20 that needed in CT imaging.\(^{52–56}\)

2.2.8 Chemical Shift-selective Imaging

In some circumstances it may be necessary to image structures that are obscured by the bright signal of fat. This may be accomplished by exploiting the fact that fat and water protons are spectrally separated by about 3 ppm. It is therefore possible to use spectral saturation techniques such as used for water suppression (as described in section 3.3). As with water suppression, a number of methods have been developed utilizing RF pulses and magnetic gradients. In one case, the fat portion of the spectrum is saturated prior to the image sequence so that no fat signal can contribute to the image. Alternatively, an inversion recovery sequence can exploit the \( T_1 \) relaxation of fat so that the 90° excitation pulse is applied when the fat signal has no longitudinal component.

2.3 Image Artifacts

An image artifact is any false feature appearing on the magnetic resonance image caused by the imaging process. The source of the artifact can be from the magnetic resonance hardware or of a physiological origin.

The causes of hardware artifacts include \( B_0 \) inhomogeneity, gradient limitations, RF inhomogeneity, and RF quadrature effects. \( B_0 \) inhomogeneity of just a few ppm leads to noticeable shading of magnetic resonance images due to \( T_2^* \) effects, whereas greater inhomogeneities give rise to spatial distortions in the image.

Artifacts arising from problems with the gradient system are very similar to those from \( B_0 \) inhomogeneity. If an abnormal current passes through one of the gradient coils, the aspect ratio of the image will be incorrect and the shape of the object will be distorted. If a gradient coil is damaged, the direction of a gradient may not remain constant, which will make the object appear bent.

An RF inhomogeneity problem causes a variation in intensity across an image. Both nonuniform RF transmission and nonuniform reception can cause artifacts. Some RF coils have inherent variations in sensitivity and will always display artifacts. For instance, a surface coil is more sensitive to tissues close to the plane of the coil and the corresponding images will show higher signal in these tissues. The presence of a nonferromagnetic metal, such as dental work, may prevent the RF energy from passing into a tissue, leaving a signal void in the image. An example of a RF inhomogeneity artifact can be seen in Figure 16(a).

**Figure 16** Examples of image artifacts arising from instrument limitations. (a) This sagittal head image displays a signal void (arrow) due to RF inhomogeneities caused by a large amount of dental work in the patient’s mouth. (b) This axial image suffers from artifacts (arrow) caused by improper RF quadrature. The alternating black and white pattern of this artifact causes it to be known as a zipper artifact. (Images courtesy of Dr. William W. Orrison, Jr, University of Utah.).
RF quadrature artifacts arise from improper operation of the two channels of the detector. If one of the amplifiers has a DC offset in its output, the Fourier transformed data can display bright or dark spots in the center of the image, as seen in Figure 16(b). If one channel of the detector has a higher gain than the other, it will result in a ghosting of objects diagonally in the image.

Some natural processes that can cause image artifacts include motion, flow and chemical shift. Motion of the entire object during the imaging sequence generally results in a blurring of the entire image with ghost images in the phase encoding direction. Movement of a small portion of the imaged object results in blurring of that small portion of the object across the image. Immobilizing the patient or imaged object can minimize motion artifacts. Frequently, however, the patient’s breathing or heartbeat causes the motion as in Figure 17(a). The solution in these cases is to gate the imaging sequence to the cardiac or respiratory cycle of the patient.

Blood flowing through a slice can experience a RF pulse and then flow out of the slice by the time the signal is recorded. This results in loss of signal from blood vessels as shown in Figure 17(b). In a multislice sequence, the slices could be positioned such that blood experiencing a 90° pulse in one slice can flow into another slice and experience a 180° rotation and into a third and contribute to the echo. In this case, the effect is usually that some slices have dark blood vessels and others have bright blood vessels.

A chemical shift artifact is caused by the difference in the resonance frequencies of fat and water. The artifact manifests itself as a misregistration between the fat and water pixels in an image. The magnitude of the effect increases with the $B_0$ field strength. At 0.5 T the effect is less than one pixel, whereas at 1.5 T the effect is approximately 2 pixels. Figure 17(c) shows an image with chemical shift artifacts. The portions of the image consisting mostly of fat are shifted slightly with respect to the portions that contain mostly water. This is most easily seen at the borders between fat and muscle.

In addition to the above causes, partial volume and wrap around artifacts may arise from improper instrument setting. A partial volume artifact is any artifact that is caused by the size of the image voxel. For example, a large voxel might contain a combination of fat and water. The signal intensity will be equal to the weighted average of the quantity of water and fat present in the voxel. Thus, resolution suffers because of multiple features present in a single-image voxel. Smaller voxels reduce partial volume artifacts by increasing the image resolution.

A wrap-around artifact is the occurrence of a part of the imaged anatomy, which is located outside of the FOV, inside of the FOV. A wrap-around artifact can be seen in Figure 17(d). This artifact is caused by the selected FOV being smaller than the size of the imaged object. More specifically, the digitization rate is less than the range of frequencies in the echo. Wrap-around artifacts are avoided by choosing a larger FOV, adjusting the position of the image center, or selecting an imaging coil that will not excite or detect spins from tissues outside of the desired FOV.

**Figure 17** Examples of naturally occurring image artifacts. (a) This coronal image of the abdomen shows severe ghosting and blurring due to the patient’s breathing during the acquisition. Such artifacts can be avoided by instructing the patient to hold their breath while the image is collected. (b) The femoral arteries in this pelvic image are black (black arrowheads) because of flow artifacts. The femoral veins (white arrows) appear bright because venous blood does not flow as quickly as arterial blood. (c) This axial image shows chemical shift artifacts (arrows), in which areas of the image representing fat are shifted relative to the areas that mainly contain water. (d) This image of the head shows a wrap-around artifact. The top portion of the head wraps around to the bottom of the image and the lower jaw and neck are wrapped-around to the top of the image. ### 2.4 Advanced Imaging Techniques

As explained above, contrast can be enhanced by producing $T_1$-weighted or $T_2$-weighted images or by administering exogenous contrast agents. Other methods of contrast enhancement utilize flow, diffusion, or susceptibility effects. Flow and diffusion phenomena can be used to produce angiographic, perfusion-weighted, or diffusion-weighted images. The effects of susceptibility changes are often exploited in functional imaging. These phenomena can produce intrinsic contrast without the toxic contrast agents used in CT, such as iodine. Because of space limitation, none of the techniques will be covered in depth.
2.4.1 Flow-sensitive and Diffusion-sensitive Imaging

Flow- and diffusion-sensitive imaging can be used to produce angiographic images, perfusion-weighted images or diffusion-weighted images. Angiographic images display the signal from blood in the lumen of large and medium size vessels. Perfusion-weighted images are sensitive to the flow of blood through the microscopic capillary vessels. Diffusion-weighted images are sensitive to changes in the random thermal motion of water in the tissue. Techniques based on relaxation times or phase contrast are used for angiographic and perfusion-weighted imaging. Phase contrast techniques can also produce diffusion-weighted images.

Relaxation techniques use contrast agents or saturation methods to mark the incoming blood and trace its progress through the vessels. Exogenous contrast agents can be injected into the circulatory system to reduce the $T_1$ time of blood relative to the surrounding tissues. When images are collected with a short TR value, the signal from the background tissues is suppressed due to its long $T_1$. Saturation techniques operate on a similar principle, but utilize endogenous spin labeling. After saturating the imaging slice, stationary tissues contribute very little signal to the image. However, the saturated spins in flowing blood are replaced by new fully relaxed spins. Therefore, an image produced shortly after saturation of the imaging slice will show only the unsaturated blood flowing into the slice.

Relaxation techniques can be used to monitor bulk flow through the macroscopic blood vessels or random flow through the capillary beds. For angiographic images the data is collected immediately following saturation or injection of contrast agent. Perfusion-weighted imaging requires a longer delay between saturation and image collection, to allow the unsaturated blood or contrast agent to enter the capillaries. These techniques cannot be used to produce diffusion-weighted images because of the incoherent nature of diffusion.

Phase-contrast methods can measure bulk flow, perfusion, or diffusion. To produce angiographic or perfusion-weighted images, phase contrast is achieved with a pulse sequence with a bipolar gradient pulse, as shown in Figure 18. A diffusion-weighted pulse sequence, as shown in Figure 19, also uses bipolar gradients. With a bipolar gradient, a positive gradient is turned on for a period of time then a negative gradient is applied for an equivalent amount of time. A bipolar gradient pulse has no net effect on stationary spins. The spins that move from one location to another will either gain or lose phase as a result of the gradients. Flow and diffusion are 3-D anisotropic processes. Therefore, phase contrast techniques must be applied in three directions. To accomplish this, images are collected with phase contrast gradients along each axis.

To produce a magnetic resonance angiographic phase-contrast image, two imaging sequences are performed in which the first has a positive bipolar gradient pulse and the second a negative bipolar gradient pulse. The raw data from the positive and negative bipolar gradient pulses are subtracted so that the signals from the stationary spins cancel, leaving only the moving spins.

Phase-contrast pulse sequences are also sensitive to perfusion. Because perfusion is random, the moving blood gains random phases. The average phase is zero, but the standard deviation of the phases is proportional to the perfusion. Plotting the log of signal intensity versus TE will yield a curve with two components. The slow component, associated with the diffusion of water in the interstitial and intracellular spaces, represents most (80–90%) of the total signal. The remaining fast

![Figure 18 Phase contrast MRI angiography pulse sequence. A gradient echo is formed at time TE by the action of the slice-selective RF pulse and gradient. The flow encoding gradient is applied along the x, y, and z directions in different image acquisitions.](image1)

![Figure 19 Pulse sequence sensitive to diffusion. Two matched but variable diffusion-weighting gradients are placed on either side of the slice-selective 180° pulse. In the absence of diffusion, these two gradients will cancel each other out and have no effect on the image. Diffusion causes dephasing of the spins which, in turn, decreases the signal amplitude.](image2)
component originates from blood flow through the capillary bed. However, exchange between the capillaries and the interstitial space can complicate the interpretation of such a plot.

Because most of the random motion in tissue is due to diffusion, only two phase-contrast images are needed with different gradient values to produce a diffusion weighted image. The ratio of the two images then yields a pixel-by-pixel map that is proportional to the diffusion coefficient. Although the gradient strength sets the sensitivity of a diffusion-weighted pulse sequence, the detectable diffusion coefficient is limited by the $T_2$ relaxation. An alternative method must be used to measure very long diffusion coefficients. Using stimulated echoes, it is possible to store the magnetization along the longitudinal axis. This allows longer diffusion times to be measured than is feasible with spin–echo pulse sequences.

Magnetic resonance angiography has been used extensively for the diagnosis of vascular disorders in the brain. A typical angiography image of the brain is seen in Figure 20. Arterial stenoses, tumor vascularity, aneurysms, and vascular malformations can be identified and characterized noninvasively by magnetic resonance angiography. The high quality of saturation techniques, also called time-of-flight methods, has made MRI the method of choice for angiography. These methods have also been used in other parts of the body including the abdominal aorta, the vessels of the pelvis, and the gastrointestinal vessels. Any imaging sequence that is sensitive to blood flow is also sensitive to motion such as respiratory motion, patient movement or cardiac motion. For this reason, MRI has not been widely used to image the arterial tree of the heart. Radiographic imaging with a vascular contrast agent is still the most common method for mapping the coronary arteries.

Although time-of-flight angiography has gained widespread acceptance, phase-contrast methods have a distinct advantage in detecting stenoses. The narrowing of a vessel causes turbulence with no coherent flow. Time-of-flight methods show the narrowing of the vessel, but they do not detect turbulence. In phase-contrast images, however, areas of turbulence are dark because of the lack of bulk motion of the blood.

All the three techniques, angiography, perfusion-weighted imaging, and diffusion-weighted imaging, can be useful for diagnosis, characterization and treatment of stroke. During a stroke, blood flow in the brain drops due to blockage in the artery. Magnetic resonance angiography can be used to locate the blocked vessel, determine the extent of blockage, and predict which areas of the brain will be affected. Diffusion-weighted imaging can be used to assess the extent of ischemic damage within 30–60 min after a stroke. A few minutes after a stroke, osmotic forces drive water into the cell causing intracellular edema, also known as cytotoxic edema. Because intracellular diffusion is slower than extracellular diffusion, cytotoxic edema decreases the average diffusion coefficient. This leads to increased signal intensity in the infarcted tissue on diffusion-weighted images. Figure 21 shows (a) proton density, (b) $T_2$-weighted, (c) $T_1$-weighted, and (d) diffusion-weighted images of the brain 12 h after a stroke. Whereas the other images show abnormal results, only the diffusion-weighted image clearly shows the extent of ischemic damage.

Following a stroke, the central area appears bright on diffusion-weighted images, but the surrounding regions

![Figure 20](image_url)  
**Figure 20** Angiographic magnetic resonance image of the brain. The background tissues are suppressed leaving only blood vessels in the image. (Image courtesy of Philips Medical Systems, Inc.).

![Figure 21](image_url)  
**Figure 21** (a) Proton density, (b) $T_2$-weighted, (c) $T_1$-weighted, and (d) diffusion-weighted images of the brain 12 h after onset of stroke symptoms. Although all four images show abnormal results, only the diffusion-weighted image clearly shows the extent of ischemic tissues. (Image courtesy of General Electric Medical Systems.).
often appear normal. On perfusion-weighted images, no perfusion can be seen in the central area.\textsuperscript{55–57} In addition, there is often decreased perfusion in the surrounding regions. This indicates a central infarcted area with decreased diffusion and no perfusion surrounded by a penumbra of normal diffusion but decreased perfusion. The penumbral regions often infarct later if not treated appropriately. Therefore, perfusion-weighted imaging can be used to prevent further ischemic damage to the brain.

In conclusion, magnetic resonance angiography can provide a detailed map of the blood vessels, allowing the blocked artery to be identified and treated. Diffusion-weighted images can be used to determine precisely the extent of ischemic tissues. Perfusion-weighted images can be used to predict areas at risk for future strokes, allowing suitable preventive treatments. Thus, all three methods can provide complementary information in the diagnosis and treatment of stroke.

2.4.2 Functional Imaging

Functional imaging can be used to study the activity of brain tissue. By monitoring which areas of the brain are stimulated under different tasks (such as visual stimulus, motor activity, auditory stimulus, mental tasks, and speech and language activities) the correlation between brain function and physical stimulation can be mapped. Most functional MRI in the brain is based upon the BOLD phenomenon.\textsuperscript{88–91} Increases in neuronal activity are accompanied by increases in blood flow, volume, and oxygenation in the surrounding tissue. This increased oxygenation exceeds the increased metabolic demands of the brain tissue, causing the concentration of oxymoglobin in the blood to rise and the concentration of deoxymoglobin to decrease. Oxymoglobin is diamagnetic, whereas deoxymoglobin is paramagnetic. Therefore, deoxymoglobin acts like an intrinsic contrast agent. The increased oxygenation lowers the local concentration of deoxymoglobin, which in turn lowers the magnetic field inhomogeneities in the blood vessels. The signal arising from these areas of the brain decay at a slower rate and therefore appear brighter in images.

The ability to perform functional brain imaging came about through the development of EPI,\textsuperscript{92} which enabled rapid imaging on the physiological timescale of brain activation. Figure 22 shows a typical EPI pulse sequence that can collect an entire image in only 0.1 s. In typical MRI, each phase-encoding step has to be individually executed to collect all the data needed for one image slice. For 256 phase-encoding steps, the pulse sequence has to run 256 times with a suitable delay between each step to avoid $T_1$ weighting. Instead of collecting the data in multiple phase-encoding steps, EPI collects all the data from a single excitation. To produce multiple echoes, the readout gradient is rapidly switched from positive to negative magnitudes. To achieve phase encoding, either the phase-encoding gradient is pulsed for each reversal of the readout gradient, or the phase-encoding gradient remains constant during data acquisition. To collect all of the data in one pulse run, the effective TEs tend to be very long. This causes the signal to be heavily $T_2^*$ weighted, increasing the sensitivity of EPI to BOLD contrast.

Functional imaging has been used to characterize neurodegenerative diseases, such as Alzheimer’s and Parkinson’s, and cognitive disorders. Functional imaging has also been applied towards patients undergoing surgery to remove brain tumors. Brain tumors are unlike most other neoplastic growths in that the degree of malignancy is not the most important factor. Instead, the location of the tumor is more relevant to determining the treatment options and probable outcomes.\textsuperscript{93} If located in a vital area of the brain, even the most benign tumors can be incapacitating or fatal. Surgery designed to remove the tumor must always weigh the benefits of removing as much of the tumor as possible against the risks of damaging essential brain tissue. Under pathological conditions, the location of brain functions may differ substantially from the normal neuroanatomic predictions. Without knowing where vital brain functions reside, the surgeon must be supremely careful in removing the tumor. However, functional MRI allows the doctor to map the exact locations of vital brain functions noninvasively before surgery. The surgeon can then make a better-informed decision, allowing the removal of the maximum amount of diseased tissue with the minimum risk of postoperative neurological deficits.

2.5 Safety Issues

Although MRI does not use ionizing radiation to produce images there are still some important safety considerations with which one should be familiar. These
relate to the use of strong magnetic fields, RF energy, and magnetic field gradients.94

2.5.1 Main Magnetic Field

The main magnetic field of a typical MRI scanner is about 30,000 times the strength of the earth’s magnetic field. This strong magnetic field can literally pick up and pull ferromagnetic objects such as stretchers, oxygen bottles, fork-lift tines, heavy-duty floor buffers, mop buckets, and so on. The force exerted on a large metal object can injure or kill an individual. It can also seriously damage the magnet and imaging coils. A magnet can also pull smaller objects such as pagers, bobby pins and pens and injure a person or distort the magnetic field homogeneity. Individuals with aneurysm clips, shrapnel or older ferromagnetic implants should not be imaged because magnetic forces can pull on these objects, cutting and compressing healthy tissue. The strong field also affects devices such as pacemakers. The magnetic reed switch in modern pacemakers is disturbed by strong magnetic fields resulting in possible deleterious effects to the patient. Some types of heart valves (e.g. Star–Edwards) are torqued in a magnetic field; however, this torque is less than the stresses that occur normally as a result of blood flow. Therefore, heart valves are not now considered an absolute contraindication for MRI. Magnetic fields will also erase the magnetic strip of credit cards and magnetic storage media. Mechanical watches will “freeze up” in a strong field, sometimes permanently. Some metallic objects that are usually safe near a MRI machine are gold jewelry and eyeglass frames. Although there is no evidence that magnetic and electric fields associated with MRI interfere with human development, caution must be exercised in MRI examination of patients who are pregnant. As with all interventions in pregnancy, MRI should be used during the first trimester when it offers a definite advantage over other tests.

The United States Food and Drug Administration (USFDA) safety guidelines state that field strengths not exceeding 2.0 T may be routinely used. Magnetic fields as large as 8 T, however, are currently employed for human research purposes. People with pacemakers must not be exposed to magnetic fields greater than 5 G. A 50 G magnetic field will erase magnetic storage media.

2.5.2 Radiofrequency RadiationRF

The RF power used in MRI is equivalent to the transmission of a small radio station (15–20 kW) and can cause heating of the tissue. The USFDA recommends that the exposure to RF energy be limited. The specific absorption rate (SAR) is the limiting measure:

\[
SAR = \text{joules of RF s}^{-1} \text{kg}^{-1} \text{body weight} = \text{W kg}^{-1}
\]

The SAR for the whole body must be less than 0.4 W kg\(^{-1}\). It must be less than 3.2 W kg\(^{-1}\) averaged over the head. Any pulse sequence must not raise the temperature by more than 1 °C and be no greater than 38 °C in the head, 39 °C in the trunk, and 40 °C in the extremities.

2.5.3 Varying Magnetic (Gradient) Fields

Time-varying magnetic fields induce electrical currents in conductors, as with an electrical generator. In patients with metallic implants, the potential exists for electrical currents to be induced in the metal, causing subsequent heating. Very rapidly changing magnetic fields, as may be achieved with EPI, have been shown to cause nerve stimulation.

The USFDA recommendations for the rate of change of magnetic fields state that the \(dB/dt\) for the system must be less than that required to produce peripheral nerve stimulation. Imaging gradients may also produce high acoustic noise due to mechanical motion of the gradients caused by switching high currents within the main magnetic field. The American Occupational Safety and Health Administration (OSHA) limits the peak acoustic noise to 200 Pa or 140 dB referenced to 20 mPa. Often, patients are instructed to wear protective earplugs to reduce the discomfort and possible hearing damage that can result from an MRI examination.

3 SPECTROSCOPY

MRS is an important aspect in the field of medical NMR, enabling much earlier identification of some diseases. With MRS, one is able to look inside the cell at its steady state metabolic processes, essentially performing a noninvasive chemical analysis. The information gathered can be interpreted spatially. As MRS is noninvasive, the same tissue can be examined again and again, thus making it an important tool in the diagnosis, prognosis and therapy monitoring of disease processes. Some of the more common nuclei that have been exploited by NMR to study biological tissue are listed in Table 2.

3.1 Localization Techniques

Clinical spectroscopy often requires the signal to be collected from only one particular area of tissue. Various methods have been devised to localize the acquired signal.

The most common techniques include surface coil acquisition, depth-resolved surface coil spectroscopy (DRESS), image-selected in vivo spectroscopy (ISIS), stimulated echo acquisition mode spectroscopy (STEAM), point-resolved spectroscopy sequence (PRESS), and chemical shift imaging (CSI).

3.1.1 Surface Coil Acquisition

One of the easiest methods of localization involves the use of a surface coil, as introduced by Ackerman et al.17 A surface coil only excites and receives signals from the immediate vicinity of the coil. By altering the size of the surface coil, the active volume can be changed. By moving the coil, a different area may be investigated. The main advantage of surface coil spectroscopy is the simplicity. No magnetic field gradients or specialized pulse sequences are required. In addition, a surface coil is one of the easiest RF coils to design and construct. A surface coil also offers superb SNR and filling factor. However, surface coils have several disadvantages. The surface coil must be in close physical contact with the tissue to be studied. This may even require the coil to be placed within the body (e.g. an endorectal coil used to study the prostate), greatly undermining the noninvasive nature of MRI. In addition, moving the coil to investigate other areas may be impractical. A surface coil does not produce a uniform RF field, being more sensitive to nearby tissues and less sensitive to deeper tissue. This may provide incomplete and unreliable localization.

3.1.2 Depth-resolved Surface Coil Spectroscopy DRESS

A DRESS sequence, as shown in Figure 23, has been developed to improve the localization characteristics of surface coils. This sequence uses a slice-selective pulse and a gradient perpendicular to the plane of the surface coil. Only nuclei in a disk-shaped volume parallel to the coil are excited and contribute signal. The thickness of the disk depends upon the bandwidth of the pulse and the magnitude of the gradient. The position is determined by the physical location within the magnet and the center frequency of the pulse. The DRESS sequence allows total suppression of signals arising from superficial tissues. This technique can be extended to acquire multislice data from the sensitive volume of the surface coil. This is called slice interleaved (SLIT) DRESS, also known by the acronym SLIT/DRESS.

3.1.3 Image-selected In Vivo Spectroscopy ISIS

The ISIS method was developed by Ordidge et al. and is based on the selective inversion of magnetization from the volume of interest. In this method, data from a selected plane is obtained by acquiring two global spectra of the entire region excited by the RF coil. As shown in Figure 24, in the first experiment, the total signal is acquired from all nuclear spins following application of a single RF pulse. The second experiment inverts the spins in the selected slice with a slice-selective 180° pulse in combination with a magnetic field gradient. After a suitable inversion delay, this preparation pulse is followed by a signal-acquisition pulse as in the first experiment. Upon subtraction of the FID from the two experiments, the signals from the selected plane are added, whereas those from outside the plane cancel each other out. In a similar way, selection of a cube is achieved by incorporating three selective-inversion pulses, each in the presence of a magnetic field gradient along the $x$, $y$, and $z$ axes. Eight experiments with different permutations of the three selective-inversion pulses are required for 3-D localization.

The main advantage of ISIS is that the spectra have very little $T_2$ weighting compared to other 3-D localization.
techniques. This allows localized spectra to be collected from metabolites with relatively short $T_2$ values, such as $^{31}$P metabolites. Because signals are collected from each area and then added or subtracted from the total signal, ISIS is very sensitive to movement. If the patient moves between one acquisition and the next, the localization will be insufficient.

### 3.1.4 Point-resolved Spectroscopy

The PRESS pulse sequence seen in Figure 25 can achieve localization within a single acquisition. The PRESS technique uses one slice-selective 90° pulse and two slice-selective 180° pulses to form a spin echo. The combination of the band-limited RF pulse and the magnetic field gradient only excites spins in a thin plane along the gradient axis. The three slice-selective pulses are aligned along the three cardinal directions, so that only spins at the intersection of these three planes contribute to the echo signal. This pulse sequence is suitable for nuclei that have long $T_2$ relaxation such as $^1$H.

### 3.1.5 Stimulated Echo Acquisition Mode

Another single-shot localization pulse sequence is STEAM. The STEAM pulse sequence shown in Figure 26 uses slice-selective pulses much like the PRESS sequence. However, STEAM uses three slice-selective 90° pulses to produce a stimulated echo from the spins at the intersection of the three planes. Because STEAM relies on the production of a stimulated echo, only half of the available magnetization can be acquired. Thus, STEAM only produces half as much signal as a PRESS pulse sequence. However, STEAM allows a shorter TE than PRESS. Therefore, when studying compounds with short $T_2$ times, such as phosphorus metabolites, a STEAM pulse sequence may be preferable.
CSI pulse sequence. Spatial encoding in three dimensions is achieved with a slice-selective pulse and two phase-encoding gradients. Because there is no frequency-encoding gradient, spectral information is retained in the acquired signal.

Figure 27

3.1.6 Chemical Shift Imaging CSI

CSI, reported by Maudsley et al.,101 and Brown et al.,102 is a technique for obtaining multiple localized spectra, simultaneously, from a set of voxels spanning the region of interest. As seen in Figure 27, it uses the same phase-encoding principles as 2-D and 3-D imaging techniques. Each spin is spatially encoded by phase-encoding gradients. There are no gradients during data collection, so frequency (spectral) information from each detectable compound is preserved. Although CSI can be used with one, two, or three dimensions of phase encoding, the simplest method is a 1-D CSI sequence with a surface coil to define the measured volume.

3.2 31P Nuclear Magnetic Resonance Spectroscopy NMR

Phosphorus NMR spectroscopy has been widely used to monitor noninvasively changes in high-energy metabolites. Several important metabolites can be observed in 31P spectra including phosphocreatine (PCr), inorganic phosphate (P_1), adenosine triphosphate (ATP), phosphomonoesters (PME), and phosphodiesters (PDE). In vivo 31P spectra from various vital organs are shown in Figure 28. The PCr resonance is normally set to 0.0 ppm. Thus, P_1 is found at 3.7–5.2 ppm, γ-ATP around −2.7 ppm, α-ATP around −7.8 ppm, β-ATP around −16.3 ppm, and PDE 2–3 ppm from PCr.

Phosphorus has been widely used because of the importance of the observed signals. The major metabolite used for biological work including muscle contraction and ion transport across the cellular membrane is ATP. It is also used for the synthesis of many other required compounds, such as carbohydrates, proteins, lipids, and nucleic acids. However, PCr is often used in the body as a high-energy storage compound. PCr and ADP combine to form ATP and creatine (Cr). Thus, depleted stores of ATP can be restored by consuming PCr and creating Cr. The ratio of PCr to ATP has historically been used as an early indication of metabolic disturbance. A drop in oxidative phosphorylation will cause a decrease in the PCr/ATP ratio, indicating an impaired energy status. 31P-NMR can also be used to quantitate tissue metabolites, calculate phosphorylation potential, measure free Mg^{2+} concentrations and measure chemical exchange.

Another strength of 31P spectroscopy lies in the fact that the chemical shift of the P_1 peak is sensitive to pH, has a pK_a value close to physiological pH, and is relatively insensitive to other ionic concentrations. In addition, P_1 shows no spin–spin coupling and is found in adequate tissue concentrations.103 P_1 is found in the intracellular compartment, so pH measurements based on the chemical shift of P_1 represent intracellular pH. The pH can be calculated from a measurement of the chemical shift of P_1 relative to another peak. The reference peak is

Figure 28 Phosphorus spectrum obtained from the skeletal muscle, heart, liver, kidney and brain. Peak assignments are as follows: 1, PME; 2, P_1; 3, PDE; 4, PCr; 5, γ-ATP; 6, α-ATP; 7, β-ATP.
generally chosen to be PCr, resulting in the Equation (4):

\[
pH = 6.75 + \log \left( \frac{\delta_{P,-PCr} - 3.28}{5.69 - \delta_{P,-PCr}} \right) \tag{4}
\]

Alternatively, the \( \alpha \)-ATP peak may be used as a chemical shift reference, leading to a slight modification (Equation 5):

\[
pH = 6.75 + \log \left( \frac{\delta_{P,-\alpha-ATP} - 10.85}{13.25 - \delta_{P,-\alpha-ATP}} \right) \tag{5}
\]

Phosphorus NMR has been used to diagnose and characterize a number of different disorders throughout the body (including the heart, skeletal muscle, and brain). In addition, the \( 31P \) signals have been used to monitor characterization of a number of different disorders throughout exercise. At rest, a low ratio of PCr to Pi may be indicative of the metabolic state of skeletal muscle both at rest and during exercise. In adult stroke, \( 31P \) spectra can be used to localize the extent of energy failure and may indicate which areas are at risk of future strokes if not properly treated.

Phosphorus NMR spectroscopy has also been applied to heart disease. For example, transplanted hearts show a significant correlation between decreased PCr/ATP ratio. In 1992, Neubauer et al. found a significant correlation between decreased PCr/ATP ratio and the New York Heart Association (NYHA) clinical classification of heart failure. Upon treatment, an improved NYHA classification was accompanied by an increase in PCr/ATP ratio.

Phosphorus NMR spectroscopy can determine the metabolic state of skeletal muscle both at rest and during exercise. At rest, a low ratio of PCr to P, may be indicative of mitochondrial myopathies, hypothyroidism, muscular dystrophy, myotonic dystrophy, denervating disorders or diabetes. Several enzyme deficiencies may also be diagnosed by \( 31P \)-NMR in conjunction with exercise. An unusually high rate of acidosis accompanied by a large drop in the PCr/P, ratio indicates a disorder in an enzyme of the oxidative pathway. This disorder causes ATP to be produced by glycolysis, forming lactic acid and, hence, causing the high rate of acidosis. Conversely, a low rate of acidosis and an increase in the PME signal indicates disruption of one of the enzymes in the glycolytic pathway. As another example, spectra obtained from patients with Mc Ardle’s syndrome show rapid depletion of PCr, a low rate of acidosis, and no increase in the PME signal. These patients suffer from a disorder in which glycogen phosphorylase is missing, blocking glycogen metabolism, and causing rapid fatigue during exercise. A phosphofructokinase deficiency can cause the PCr peak to decrease, the Pi peak to increase, and the PME peak to increase with no acidosis during exercise.

\( 31P \) spectroscopy may be used as a screening tool to detect these disorders in neonates, allowing immediate administration of appropriate treatments.

Phosphorus spectroscopy has also been applied to a wide range of clinical applications in the brain. After birth asphyxia, a \( 31P \) spectrum of the newborn brain shows reduced energy state and is predictive of outcome. In adult stroke, \( 31P \) spectra can be used to localize the extent of energy failure and may indicate which areas are at risk of future strokes if not properly treated.

Phosphorus NMR has also been used in the study of tumor diagnosis, progression and therapy. For many years tumors were assumed to have an acidic pH due to the conversion of carbohydrate into lactic acid. The advent of \( 31P \)-NMR for noninvasive measurement of pH, however, has shown that tumors have an alkaline pH. In addition, many human tumors show low PCr, high PME, and high PDE signals. Changes in the \( 31P \) spectra may be used to predict and monitor response to radiotherapy or chemotherapy. There is currently a 5-year-eight-center study underway to determine the utility of \( 31P \) during cancer treatment.

### 3.3 Water Suppression and \( 1H \) Spectroscopy

Proton NMR spectroscopy has historically lagged behind \( 31P \) spectroscopy despite the superior sensitivity and ease of application on clinical scanners. The fundamental difficulty in proton spectroscopy lies in the fact that the water \( 1H \) signal, representing a concentration of 80 M in body tissues, greatly overshadows the signals arising from metabolites, often found in concentrations of about 1 mM. To achieve reasonable resolution of these small metabolite signals, the water signal must be suppressed from the spectrum. To exploit the high sensitivity of proton NMR spectroscopy clinically, many water-suppression techniques have been developed.

A common method of water suppression is selectively to saturate the water signal prior to obtaining the NMR spectrum. This technique, called presaturation, requires a low-power RF pulse to be applied for a long duration followed by the normal spectroscopy sequence. The presaturation pulse must selectively excite only the water region of the spectrum. The pulse sequence then only excites the signals away from the water signal. Presaturation is very attractive for its simplicity and ease of implementation. However, this technique also saturates signals close to the water peak. In addition, the exchangeable protons are also saturated and cannot be studied. Care must also be taken because presaturation pulses raise the SAR and may cause significant heating.
Another method of water suppression uses specialized RF pulses selectively to excite all of the signals except for the water. These pulses are sometimes called binomial pulses, but many variations exist. The pulse is designed to sum to an effective 0° pulse for water, but a 90° pulse for all other signals. As the water is not saturated, exchangeable protons are visible by this method. Heating and RF safety concerns are not limiting factors as they are with presaturation methods.

A popular water suppression method that utilizes both selective pulses and magnetic field gradients is known as CHESS (chemical shift selective saturation). A frequency-selective 90° pulse is applied to only the water signal followed by the application of a gradient that dephases the water signal. After repeated application of frequency-selective 90° pulses and gradients, very little water signal is detected. This method is easily implemented on most clinical scanners and reduces exposure to RF radiation.

The brain is ideal for 1H-NMR studies because it is relatively stationary, uniform, spherical, and has low lipid concentrations within the tissues. Representative 1H-NMR spectra with water suppression from normal and abnormal brain tissue are seen in Figure 29. Several biomedically important metabolites can be seen in these spectra.

The most intense peak in the 1H spectrum from the normal brain is NAA at 2.02 ppm. As NAA is thought to exist only in neuronal cells, it can be used to grade neuronal loss. Little or no NAA is found in brain tumors or ischemic tissues following a stroke as seen in Figure 29. In addition, levels of NAA decrease during progression of demyelinating diseases. Levels of NAA can be significantly altered in diseases such as multiple sclerosis, HIV, and epilepsy. Analysis of NAA signal intensity can be complicated by several other resonances that overlap the NAA peak. In particular, the C(3) glutamate and glutamine peaks can add a significant amount of signal in spectra collected with short TE times. These contributions can be corrected by deconvoluting the NAA peak with overlapping glutamate and glutamine peaks. The NAA peak also overlaps with N-acetyl glutamate in white matter.

Another large signal in the 1H spectrum arises from Cho at 3.2 ppm. Cho is a component of the phospholipid metabolism and is found in cell membranes. The Cho peak may indicate membrane synthesis and cellular density. Increased Cho levels are found in tumors as seen in the spectra of Figure 29. Cho is also elevated in metabolic white matter diseases and multiple sclerosis. Demyelinating diseases are often associated with increased levels of Cho.

This may indicate that Cho can be released from NMR-invisible stores in myelin.

However, the Cho peak contains signals from free Cho, glycerol 3-phosphorylecholine, and phosphorylecholine. Additional metabolites, such as phosphatidyl Cho, taurine, or betaine, may be found at 3.2 ppm under certain pathophysiological conditions. Analysis of 1H and 31P spectra may help separate some of the different contributions.

Lactate has been one of the most popular metabolites in 1H spectroscopy. The lactate methyl doublet resonates at 1.33 ppm. Lactate, as a product of glycolysis, is used as an indicator of insufficient O2 supply. As seen in Figure 29, very little is found in normal brain tissue, but lactate levels may increase 10–20 times in acute ischemia, such as immediately following a stroke, or as
a result of chronically reduced perfusion, such as found in tumors. The regions of highest lactate content correspond with lowest NAA levels after stroke, correlating greatest neuronal loss with the areas suffering from the lowest O$_2$ supply. Changes in lactate can also be used to monitor tumor growth or response to therapy. Macrophages are also believed to produce large amounts of lactate. As macrophages quickly infiltrate the damaged tissue and remain for prolonged periods, lactate levels may rise accordingly.

Cr, a metabolic marker, is seen at 3.03 ppm in 1H spectra. Other resonances are also found at this chemical shift including PCr, γ-aminobutyric acid (GABA) and cytosolic macromolecules. Like NAA, the Cr resonance is decreased in the infarcted brain spectrum in Figure 29, indicating reduced metabolic activity. Cr levels can also be used to characterize tumor metabolism. Hypometabolic tumors show increased levels of Cr while hypermetabolic tumors show lower levels.

In addition to analysis of elevated signals, the ratio of one signal to another can be used in the diagnosis. For example, spectra from AIDS patients show a characteristic reduction in the ratio of NAA to Cr and an increase in Cho to Cr. These spectroscopic changes may be more sensitive to brain lesions than conventional MRI methods. Proton NMR has shown great promise towards distinguishing between low-grade and high-grade primary brain tumors. The degree of Cho elevation, lactate formation and reduction in Cr has been used to discriminate between various types of tumors. Preul et al. correctly classified 104 of 105 proton spectra from normal volunteers and patients with the five most common adult supratentorial brain tumors using pattern recognition analysis.

3.4 Carbon-13 Spectroscopy and Decoupling
Historically, complex metabolic pathways have been studied using radioactive carbon isotopes such as $^{13}$C and $^{14}$C. These techniques require several chemical or biochemical manipulations including quenching the cellular reactions, chromatographic separation, and carbon by carbon degradation of specific metabolites. $^{13}$C-NMR spectroscopy can yield similar information without the need for such complex maneuvers.

Carbon-13 is a stable carbon isotope with spin 1/2 and 1.1% natural abundance. The low occurrence of natural $^{13}$C is both an advantage and a disadvantage. The low natural abundance yields low signals without enrichment, causing low SNRs and/or very long acquisition times. With the addition of enriched substrates, however, the lack of naturally occurring $^{13}$C is a benefit. There is little interference from background signals and practically all of the signal observed can be assumed to originate from enriched substrates. Carbon-13 can be substituted into metabolic substrates without altering their chemical characteristics to follow metabolic pathways, measure the rates of specific pathways or to detect deviations from normal metabolism. Despite the low sensitivity of $^{13}$C-NMR, in vivo human experiments have been performed. To obtain a greater SNR, tissue extraction for high-resolution spectroscopy may be required.

NMR spectroscopy can reveal molecular structures through a phenomenon known as spin–spin coupling, also called J coupling or scalar coupling. Nuclei connected by chemical bonds exchange information about their magnetic states, causing a peak to split into a particular pattern of multiple smaller peaks. The separation between the peaks in these patterns is independent of the field strength. Therefore, spin–spin coupling is reported in terms of hertz. Homonuclear coupling occurs between two nuclei of the same species, that is, $^{-13}$C$^{13}$C. Heteronuclear coupling occurs between two nuclei of different species, that is, $^{-1}$H$^{13}$C. Chemically equivalent nuclei, however, do not produce spin–spin coupling. Heteronuclear coupling between protons and $^{13}$C nuclei decreases the signal intensities of $^{13}$C resonances. This reduces the available SNR and increases the complexity of $^{13}$C spectra. Decoupling is achieved by supplying power at the $^{1}$H frequency while collecting data at the $^{13}$C frequency. This collapses the $^{13}$C signals arising from single lines, increasing the SNR of the spectrum. A number of decoupling schemes, such as WALTZ (for wideband alternating phase low-power technique for zero residue splitting) and MLEV (named after the developer of the technique, Malcolm H. Levitt), are available to decouple a wide range of $^{1}$H frequencies. In addition, low power at the $^{1}$H frequency can be applied in continuous wave mode at all other times to induce the nuclear Overhauser effect (NOE) causing a further increase in the SNR. To collect proton-decoupled $^{13}$C spectra, either a dual-tuned $^{-1}$H$^{13}$C coil or two separate singly tuned coils must be used.

Carbon-13 NMR has been used to detect natural abundance glycogen in the calf, liver, and brain. As the principal means of carbohydrate storage in humans, glycogen provides a reservoir of glucose during strenuous muscular activity. The synthesis and degradation of glycogen plays a major role in the regulation of blood glucose levels during various metabolic conditions, such as rest, exercise, fed and fasted states.

Several inherited enzyme defects can lead to glycogen storage diseases. For instance, type IIIA glycogen storage disease causes increased glycogen concentrations in the liver and muscle and abnormal glycogen structures with short outer branches. In healthy normal subjects, the $^{13}$C concentration of glycogen is of the order of 0.7–1.4 mM which borders the limit of NMR sensitivity.
Trained athletes or normal untrained subjects with special diets have increased glycogen concentrations detectable by NMR. In contrast, patients with type IIIA glycogen storage disease have approximately 2–3 times the amount of glycogen compared with trained athletes or subjects with special dietary preparation. In addition, the spectra obtained from patients with type IIIA glycogen storage disease show extra signals presumably due to the abnormal glycogen structure.\(^{178}\) The conventional procedure for measuring glycogen levels is needle biopsy,\(^{184,185}\) which is uncomfortable and may not reliably reflect changes during an extended sequence of events.

Carbon-13 NMR spectroscopy has also been applied to metabolism in the heart. The heart uses a mixture of fatty acids, lactate, and ketones to provide acetyl-CoA (coenzyme A) for entry into the citric acid cycle. The predominant substrate and the rates of metabolic flux are related to the health of the tissue.\(^{186,187}\) Carbon-13 NMR allows distinction of normal from ischemic myocardium based upon the metabolic characteristics of the tissue. These methods may also be useful for prediction of a tissue’s tolerance to ischemia. Suppression of fatty acid utilization has been shown to improve functional characteristics after reperfusion.\(^{188,189}\)

A simple and straightforward analysis can be made from the homonuclear \(-^{13}\)C\(^{13}\)C coupling patterns observed in \(^{13}\)C spectra. As \(-^{13}\)C\(^{13}\)C coupling patterns must be resolved, this method has only been performed with chemical extracts and isolated perfused organs to achieve high magnetic field homogeneity and SNR. This technique is known as isotopomer analysis.\(^{190,191}\) For instance, with metabolism of \([1,2-^{13}\)C\]acetate and \([3-^{13}\)C\]lactate, the C(4) resonance of glutamate appears as nine lines that are due to \(-^{13}\)C\(^{13}\)C coupling. Figure 30 shows a spectrum from an extract illustrating the resonance pattern including a singlet, C(4)S, two doublets with slightly different coupling constants, C(4)D34 and C(4)D45, and a quartet, C(4)Q. Two signals, C(4)S and C(4)D45, arise only from glutamate that is not enriched in the C(3) position. The other two signals, C(4)D34 and C(4)Q, can only arise when C(3) is enriched with a \(^{13}\)C nucleus. The sum of the C(4)S and C(4)D45 resonance areas versus the sum of the C(4)D45 and C(4)Q resonance areas provides a direct measurement of the relative utilization of \([3-^{13}\)C\]lactate versus \([1,2-^{13}\)C\]acetate.\(^{192}\)

### 3.5 Sodium-23 Spectroscopy

Healthy cells maintain an intracellular Na\(^{+}\) concentration of 10–25 mM against an extracellular Na\(^{+}\) concentration of 150 mM. The transmembrane Na\(^{+}\) gradient is regulated to a large part by the action of the \(-\)Na\(^{+}\)K\(^{+}\) ATPase, which pumps three Na\(^{+}\) ions out and two K\(^{+}\) ions in for each ATP molecule. The Na\(^{+}\) gradient is required to drive many vital cellular processes, including maintenance of cell volume, facilitated transport of other ions and metabolites, contractile function, and transmission of nerve impulses. Many diseases, including hypertension,\(^{193}\) manic depression,\(^{194}\) cystic fibrosis,\(^{195}\) cancer,\(^{196}\) and sepsis\(^{197}\) are associated with disruption of the transmembrane Na\(^{+}\) gradient due to alterations in ion transport and exchange processes. Several methods have been developed to study Na\(^{+}\) in biological samples, such as ion-selective microelectrodes, electrophysiological X-ray analysis, fluorescent dyes, and whole tissue analysis.\(^{196–198}\) However, only NMR has the potential for measuring Na\(^{+}\) noninvasively.

Unlike the nuclei discussed so far, Na\(^{+}\) has a spin quantum number of \(\frac{3}{2}\), resulting in biexponential \(T_2\) relaxation in biological tissues. The fast relaxation component is of the order of 2 ms and represents up to 60% of the entire Na\(^{+}\) signal. Civan and Shporer reported that 60% of the sodium in biological samples was invisible.\(^{199}\) This may indicate that the percentage of sodium in biological samples with short \(T_2\) relaxation cannot be detected with long spectrometer delay times or with long TEs. However, recent studies have shown identical results between NMR and conventional quantitative analysis, proving that Na\(^{+}\) is 100% NMR visible.\(^{200}\)

Because Na\(^{+}\) exists only as an aqua cation in tissue, both intra- and extracellular Na signals are coincident.

---

**Figure 30** Typical \(^{13}\)C spectrum collected from a tissue extract for isotopomer analysis. The resonance pattern shows a singlet, C(4)S, two doublets with slightly different coupling constants, C(4)D34 and C(4)D45, and a quartet, C(4)Q. (Spectrum courtesy of Dr. Craig R. Malloy, University of Texas, Southwestern Medical Center.)
To study the transmembrane Na\(^+\) gradient, the intracellular and extracellular signals must be separated. Three common methods to differentiate between intra- and extracellular 23Na utilize paramagnetic shift reagents, relaxation differences and multiple quantum (MQ) filters.

Paramagnetic shift reagents alter the chemical shift of extracellular 23Na relative to intracellular 23Na. The shift reagent thulium-1,4,7,10-tetraazacyclodecane-1,4,7,10-tetrakis(methylene phosphonate) (TmDOTP\(^{5-}\)) can be used to separate intra- and extracellular 23Na signals in animal experiments,\(^{200-204}\) but no shift reagent is currently available for clinical use.

Hilal et al. used differences in relaxation times to distinguish between intra- and extracellular Na\(^+\) in brain tumors.\(^{205}\) Tumors are known to have increased concentrations of intracellular Na\(^+\). The higher Na\(^+\) concentration is needed to maintain proliferation and is related to the grade of malignancy.\(^{206}\) Because of the high intracellular protein content, intracellular Na\(^+\) has a faster \(T_2\) decay than extracellular Na\(^+\).\(^{199,207}\) Hilal et al. used images derived from FIDs and various TEIs to map the fast decay fraction of tissues.\(^{205}\) They produced putative intracellular Na\(^+\) maps from the fraction of fast-decaying 23Na and saw an excellent correlation between the putative intracellular Na\(^+\) and tumor grade. They were able to differentiate between tumors, radiation necrosis, gadolinium-enhanced benign lesions, and gadolinium-enhanced malignant lesions. They reported that highly malignant gliomas (grade III) have intracellular Na\(^+\) concentrations in the range 75–55 mM, whereas low-grade gliomas (grade I) have intracellular concentrations of 35–45 mM.

These sodium maps have shown several advantages compared to the conventional methods of proton MRI. The sodium techniques frequently reveal a much larger tumor than seen by proton MRI even with Gd-DTPA enhancement. The putative intracellular sodium images show high sodium concentrations only in neoplastic tissue. Edema, radiation necrosis and postoperative changes do not show up as bright areas. However, on \(T_2\)-weighted proton images, tumor, edema, and radiation necrosis are all hyperintense regions. Sodium MRI allows distinction between neoplastic and inflammatory tissues when proton MRI cannot resolve the two areas even with Gd-DTPA enhancement.\(^{205}\)

The third method for discriminating between intra- and extracellular Na\(^+\) uses MQ filters. As Na\(^+\) has a spin quantum number of 3/2, there are four possible energy levels. This leads to three possible single quantum transitions, that is, \(3/2 \leftrightarrow 1/2, -3/2 \leftrightarrow -1/2\) and \(1/2 \leftrightarrow -1/2\). There are two possible double quantum transitions, that is, \(3/2 \leftrightarrow -1/2\) and \(1/2 \leftrightarrow -3/2\). There is also one triple quantum transition, that is, \(3/2 \leftrightarrow -3/2\). The high concentration of macromolecules in the intracellular environment causes MQ transitions to originate mainly from Na\(^+\) in the intracellular spaces. For this reason, MQ filters have been proposed to detect intracellular Na\(^+\),\(^{208}\) although some MQ-filtered signal does arise from the extracellular space.\(^{209-211}\) In contrast to the single quantum Na\(^+\) signal, however, the majority of the MQ signal comes from the intracellular space. In addition, the MQ-filtered signal is relatively insensitive to changes in extracellular Na\(^+\) content.\(^{212}\) These two facts lead to the MQ-filtered signal being useful for detecting and monitoring changes in intracellular Na\(^+\). The low SNR available with MQ-filtered 23Na-NMR has been the major obstacle in biological and clinical applications. Despite these difficulties, Dr. Boada at the University of Pittsburgh Medical Center has obtained triple quantum filtered 23Na images of the human brain in about 18 min using a 3 T magnet. Representative single quantum and triple quantum filtered images can be seen in Figure 31.

### 3.6 Fluorine-19 Spectroscopy

Another nucleus that has been used is 19F. Several advantages are associated with 19F-NMR, such as 100% abundance, higher sensitivity than 31P, wide spread of chemical shifts eliminating overlapping peaks, and no intrinsic background signals.\(^{213-215}\) Fluorine-19 NMR has been used to monitor the metabolism of fluorinated medications. In particular, 5-fluorouracil (5-FU) can be detected as well as some of its metabolized products, including fluoro-β-alanine (FBAL) and some fluoronucleotides. Figure 32 shows 19F spectra obtained from the liver of cancer patients during 5-FU treatment. The metabolism of 5-FU into FBAL is clearly seen. Thus, 19F-NMR can be used to predict and monitor response to 5-FU therapies.\(^{216-219}\)

Perfluorocarbons have historically been produced as potential blood substitutes. These compounds can be easily detected by 19F-NMR. These compounds are

![Figure 31](image-url)
also sensitive to many physiological parameters, such as oxygen tension, temperature, and pH.\textsuperscript{213–224} The paramagnetism of oxygen alters the $T_1$ relaxation of the perfluorocarbon. The chemical shifts of various signals can also be dependent upon the temperature and/or the pH.

### 4 CONCLUSIONS

The application of NMR to the field of medicine has caused an explosion of new techniques and methods. The noninvasive nature of NMR has allowed stunning advancements in imaging the human body and investigating the biochemical properties of tissues. The distinct advantages of MRI over other imaging methods has caused it quickly to become the standard technique for imaging the brain, spinal cord, spine, joints, and other anatomical structures. The development of angiographic and functional imaging techniques proves that MRI is still developing and promises future advancements. Although not as routine as MRI, NMR spectroscopy has also proven useful in detecting and characterizing a wide variety of disease states. Although biomedical NMR is a young field it has gained unprecedented acceptance and is the method of choice for a wide variety of medical applications.

Magnetic resonance spectroscopic imaging (MRSI) is a technique for producing spatially resolved maps or images of different chemicals that are found in the body or tissue. These chemicals may be naturally inherent or may be introduced by injection, but they must be detectable by the magnetic resonance (MR) process (i.e., they must have nuclei that have a magnetic moment, and are mobile enough to give a free-induction decay (FID)). The MRSI technique is based on many of the same principles that are used for conventional magnetic resonance imaging (MRI) and also uses much of the same equipment as MRI. This chapter focuses on multinuclear applications of MRSI such as phosphorus-31, carbon-13, fluorine-19, sodium-23, xenon-129, helium-3, and boron-11. The MRSI method is an important technique for noninvasive measurement of biochemical and physiological changes in health and disease.

1 INTRODUCTION

An MR spectrum of nuclei such as $^{31}$P or $^{13}$C usually contains many peaks or resonances, and each resonance signal arises from the nuclei that are in slightly different local magnetic fields due to the molecular environment. This process is called chemical shift and is described in depth by Gadian. In spectroscopic imaging, the resonances of the spectrum can be separated either by pulse sequences, designed to zoom in to a specific resonance of the spectrum, or by post-processing techniques. These different spectral separation procedures are discussed in section 2 of this article. A chemical of the body may have several resonances in the MR spectrum which can be used for imaging. For example, adenosine triphosphate (ATP) gives rise to three main resonances in the $^{31}$P spectrum due to the different molecular environment of the three different phosphate groups in ATP. Each of these three resonances can be imaged, provided that there is sufficient spectral resolution for peak separation. In the case of ATP spectroscopic imaging, images can be created by line-fitting all of the resonances that belong to ATP and combining them into a single concentration value for each spatially resolved voxel. There are also chemicals and spectra that have only one resonance, such as boron-11.

Spectroscopic imaging is sometimes called chemical shift imaging (CSI) and was first developed by Brown et al. in 1982. They described a pulse sequence that used phase-encoding gradients to spatially encode the MR signal, but acquired the rf (radiofrequency) signal without a readout gradient. Thus MRSI works by combining spectroscopic and imaging techniques into a single pulse sequence. Spectroscopic imaging also has greater signal-to-noise than single voxel techniques because the MR signal comes from the whole volume being imaged. Single-voxel spectroscopy (or point-by-point spectroscopy) suffers from the low sensitivity that occurs in all point-imaging techniques. Lauterbur et al. in 1975 described a technique for using the increased sensitivity of whole-volume imaging combined with chemical shift spectroscopy. Spectroscopic imaging is basically a technique for mapping the magnetic field distribution which is sensitive to changes in the magnetic field due to chemical shift. In 1979, Maudsley et al. developed a technique for mapping the magnetic field distribution but did not label it as spectroscopic imaging or CSI. This technique is quite similar to the MR techniques used in CSI. One main difference
between conventional MRI (used for clinical diagnosis) and MRSI is in the pulse sequence (a pulse sequence is software written to control the hardware of the MR process such as the rf transmission, rf signal reception, and \( x, y, \) and \( z \) magnetic field gradients). The pulse sequence used for conventional MRI is designed to image the single resonance of the proton nuclei in water and, as water is usually over a hundred times more concentrated than other hydrogen-containing compounds, no spectral-separation techniques are needed (except in the case of lipid suppression). Also for conventional MRI, a readout magnetic field gradient (a magnetic field gradient causes a linear change in the strength of the magnetic field in one spatial direction and is superimposed on the main magnetic field) is turned on during the acquisition of the rf signal. This readout gradient spreads out the frequencies of the water signal over several thousand cycles per second (Hz), so that the chemical shift information is almost completely obscured by the gradient. However, in spectroscopic imaging, chemical shift information can be preserved by acquiring the rf signal (FID) without a readout gradient. In order to obtain a high-quality MR spectrum, the main magnetic field needs to be very homogeneous and this allows spectral separation of the different resonances in the spectrum. If there is only one resonance in the spectrum then a readout gradient can be used in the pulse sequence to spatially map the chemical.

### 2 TECHNIQUES FOR SPECTROSCOPIC IMAGING

#### 2.1 Hardware

The hardware for nonproton MRSI is much the same as used for conventional proton MRI. The hardware required here must include electronic components that are necessary for multinuclear MR spectroscopy and MRI. The common components of multinuclear MR spectroscopy and conventional MRI include the main magnet, the magnetic field gradient coils and amplifier, the computer, and digital-to-analog controller boards for each channel. However, the components that are different for multinuclear MRSI include the rf receiver and transmitter coils and the rf amplifier. For MRSI and single-voxel MR spectroscopy, rf coils are constructed (using resistors, capacitors, and inductors) to match the impedance and to tune the frequency to coincide with the resonant frequency for the specific nuclei of interest. For example, at 1.5T, \(^{31}\text{P} \) resonates at 25.8 MHz, \(^{13}\text{C} \) at 16.05 MHz, \(^{19}\text{F} \) at 60.08 MHz, and \(^{11}\text{B} \) at 20.5 MHz. There are also commercial rf coils available that are double-tuned for both protons and the main nuclei of interest (hereafter referred to as the \( x \) nuclei, such as \(^{31}\text{P} \) or \(^{13}\text{C} \)). The rf amplifier needs to be broad-band enough in rf frequency to tune to each of the frequencies listed above. The ability to detect both protons and the \( x \) nuclei is necessary in MRSI because the stronger signal strength of the protons is used for real-time adjusting of the magnetic field homogeneity (hereafter referred to as shimming). Therefore, two rf channels are used so that one channel can be switched to protons during the shimming process and then switched to the \( x \)-nucleus channel for main signal acquisition. Another reason for having two rf channels is for proton-decoupling the \( x \) nuclei (proton-decoupling is commonly used for both \(^{31}\text{P} \) and \(^{13}\text{C} \)). The reason for decoupling the protons is to obtain spectra with higher signal-to-noise and also reduce the spectral splitting caused by \( j \) coupling (\( j \) coupling is caused by energy exchange between adjacent nuclei). For example, in molecules containing a \(-\text{CH}_3\) group, the \(^{13}\text{C}-\text{NMR} \) (nuclear magnetic resonance) spectrum will show this methyl carbon split into four peaks with the overall intensity also split among the four peaks at a ratio of 1:3:3:1. However, if this same molecule is measured with proton decoupling, there will be a single \(^{13}\text{C} \) spectral peak with much higher intensity than the coupled spectrum. In proton-decoupling schemes, the proton channel is switched on and off even during pulse sequence. For rf signal detection, investigators have used surface coils,\(^{11}-^{13}\) bird-cage coils,\(^{14}-^{16}\) and saddle coils\(^{17}\) for spectroscopic imaging.

#### 2.2 Fourier Methods with Phase-encoding Gradients

CSI as proposed by Brown et al.\(^{12}\) is performed using a pulse sequence with phase-encoding gradients. An example of a CSI pulse sequence is shown in Figure 1. In this pulse sequence, an excitation rf pulse places the net magnetic vector of the spins in the \( x-y \) plane, then the phase-encoding gradients are used to spatially encode the MR signal, and finally the MR signal is acquired without any gradients. This pulse sequence allows the chemical shift information of the MR signal to be preserved while the phase of the spins has been spatially encoded (the processing of this raw MR signal is discussed in section 2.3). This basic pulse sequence can be modified in the following several ways:

1. The excitation rf pulse can be either broad-band enough to excite the whole sample (not shown) or narrow band (sin/\( x \) pulse) combined with a magnetic field gradient for slice selection (as shown in Figure 1). Using this same concept, CSI can be combined with pulse sequences such as the 90–180 spin-echo (shown in Figure 1), with point-resolved echo spectroscopy (PRESS; for cubic localized volume)\(^{18}\) or with stimulated echo acquisition mode (STEAM; for cubic localized volume)\(^{19}\).
Figure 1. CSI pulse sequence using a spin-echo excitation, slice selection, and two dimensions of phase-encoded gradients (for encoding two dimensions of space).

2. The phase-encoding gradients can be used to encode spatial information in one, two (as shown in Figure 1) or three orthogonal directions, typically called the x, y, and z directions, where x is the subject’s left to right direction, y is the subject’s anterior to posterior direction (front to back), and z is the subject’s superior to inferior (head to toe).

3. The spatial resolution of the spectroscopic imaging process can be controlled by the number of phase-encoded gradients for each spatial direction (typically, between 8 and 16 phase-encoded gradient steps are used).

4. Preparatory pulses can be added before the first rf excitation pulse for peak suppression, spatial suppression, or for spectral editing.

In a typical experiment, the pulse sequence is executed 16 times, while the x phase-encode gradient is incremented (the y phase-encode is held constant for the 16 x-value increments) and this whole set of steps is repeated 16 times for each y phase-encode step (i.e. a nested loop). Therefore, the total number of repetitions of the pulse sequence is 16 x 16, which is 256.

Each time the pulse sequence is executed for a unique set of x and y phase-encoded gradient values, the MR signal is digitized and stored on computer disk as a row of data. When the experiment is done there are 256 rows of raw time-domain data.

Computer processing of this data is used to reconstruct the spatial and chemical shift information from the time-domain MR signal. One possible algorithm has the following steps:

1. read and sort the raw data into a three-dimensional (3D) array of size (256,16,16);
2. filter with apodization and Fourier transform the data in the chemical shift dimension and put the result back into the 3D array;
3. filter with a Gaussian or sine-bell function and Fourier transform the data in the x direction;
4. filter with a Gaussian or sine-bell function and Fourier transform the data in the y direction;
5. form metabolite images or maps from each resonance of interest (this procedure is described in section 2.6).

2.3 Spectroscopic Imaging with Selective Irradiation

Bottomley et al. developed a technique for imaging single resonances of the MR spectrum. This technique has the advantage of shorter acquisition times compared to conventional CSI because a read-out gradient can be on during the acquisition of the signal. However, this technique has the disadvantages of less signal-to-noise and also only one resonance can be scanned at a time compared to conventional CSI which is spatially localized with phase-encoded gradients (described in section 2.2). Here is how the pulse sequence works:

1. A chemically selective rf pulse is used to excite the resonance of interest and consists of a narrow-band rf pulse which is applied in the absence of imaging gradients.
2. Spatial mapping is achieved with imaging gradients for slice-selection, phase-encoding, and readout, as used in conventional MRI.

Other investigators have used chemical shift selective (CHESS) MRI to study protons and also phosphocreatine (PCr). Ernst et al. were able to perform direct imaging of PCr and inorganic phosphate (Pi) with or without selective excitation of PCr in the human brain and limb.

2.4 Spectroscopic Imaging of Nuclei with Extremely Short Spin–Spin Magnetic Resonance Relaxation Time

For imaging nuclei such as boron-11 with T2 (spin–spin relaxation time) values less than 1 ms, spin echoes with phase encoding is not the best method because the MR signal will die out before the echo signal can be measured. Also, with only one peak visible in vivo, techniques for multiple-peak spectral acquisition are unnecessary for chemicals such as borocaptate sodium (BSH); therefore Glover et al. developed a technique that uses
three-dimensional projection reconstruction (3DPR) to image boron in vivo. In this case, BSH was imaged because of its use in boron neutron capture therapy (BNCT) which is a treatment for brain cancers such as glioblastoma multiforme. The 3DPR technique has the advantage over CSI methods because acquisition of the MR signal can take place immediately after the rf excitation pulse. Lauterbur proposed the use of projection reconstruction for MRI in 1973. \cite{28} Projection reconstruction is performed by measuring the MR signal in the presence of a readout gradient (which is Fourier transformed to give a spatial projection in one dimension), then the spatial direction of the readout gradient is varied in three dimensions to acquire several projections. These one-dimensional projections are then processed by a filtered back-projection, in order to spatially reconstruct the image.

### 2.5 Echo-planar Spectroscopic Imaging

Although fast spectroscopic imaging techniques such as echo-planar spectroscopic imaging (EPSI) have been mainly used for protons,\cite{29–31} there are a few published uses of EPSI for nonproton use.\cite{32,33} Spectroscopic imaging techniques that use phase-encoding gradients for all spatial localization suffer from long encoding times. Mansfield developed a rapid spectroscopic imaging technique called EPSI that used a much faster encoding scheme and employed spatial encoding interleaved into the spectral acquisition.\cite{34} The EPSI technique uses echo-planar gradients during the acquisition of the FID MR signal and allows multiple points of $k$-space (a term used to describe the two- or three-dimensional space or matrix for the raw time domain MRI data before the Fourier transform; it includes the phase-encoded and readout-encoded dimensions) to be collected during one cycle of the pulse sequence (during one repetition time of the MR pulse sequence (TR) period). One example of this technique to achieve two spatial dimensions and one chemical shift dimension is described by Posse et al.\cite{31} In this example, a slice-selective spin-echo signal is excited with a 90-tau-180 sequence (where 90° is the flip angle of the first transmission rf pulse; tau is the delay between the two pulses and 180° is the flip angle of the second transmission rf phase) and then a square-wave (echo-planar) gradient is turned on during the acquisition of the MR signal. This results in an MR signal with both spatial and chemical shift information (each individual echo contains the spatial information and the overall evolution of the signal contains the chemical-shift information). A phase-encoding gradient (in an orthogonal direction to the echo-planar gradient) is used to give another spatial dimension. After all the phase-encoded MR data is collected (during several TR periods), the MR data is sorted into a 3D array so that a three-dimensional Fourier transform (3DFT) can be performed. Other examples of EPSI have been described.\cite{35–39}

### 2.6 Data Analysis Algorithms for Spectral Quantification

For spectroscopic imaging, there are usually too many spectra for manual quantification of peak areas; therefore, automated techniques have been developed for processing the raw data.\cite{40,41} The following steps can be performed to generate a metabolite map, that is, an image of a specific chemical from the spectrum, from phase-encoded CSI:

1. Filter and Fourier transform the raw data to obtain spatially localized spectra (in the example above, there was a 3D matrix containing two dimensions of spatial information and one dimension of chemical shift information).

2. Phase each spectrum (i.e. make each resonance have a symmetric Lorentzian absorption-mode shape, as opposed to a dispersion-mode shape).

3. Reference the $x$ axis so that each resonance can be identified based on the frequency scale.

4. Evaluate the area under the curve of each peak either by peak integration or by curve fitting methods.\cite{40} Other spectral parameters that can measured and mapped include the frequency (relative to a specific peak), line-width (related to the T2), and phase of each peak.

5. Create a color or gray-level map from the peak area which was measured at each spatially resolved location (voxel).

Nelson and Brown developed an automated technique for peak detection and evaluation of peak areas called PIOABLE.\cite{42} Barker et al. have reported the use of a nonlinear least-squares fitting routine (NLLS) for determining the amplitude, decay time, frequency, and phase of each resonance in the $^{31}$P spectrum.\cite{43} They were able to fit the following seven resonances: phosphomonoester (PME), Pi, phosphodiesters (PDEs), PCr, and the $g$, $a$, and $b$ resonances of ATP.\cite{43} Van den Boogaart et al. have reported on the use of two frequency domain methods (peak area integration and Lorentzian fitting (FITSPEC)) and two time domain methods (VARPOR and HLSVD) for in vivo $^{31}$P-MRS (magnetic resonance spectroscopic) quantification.\cite{44} Several other methods are available for spectral quantification.\cite{12,41,45–50}
3 APPLICATIONS OF SPECTROSCOPIC IMAGING

3.1 Phosphorus-31

Phosphorus-31 MRSI can be used to study metabolites involved in energy metabolism such as ATP, PCr, Pi and sugar phosphates. In addition, $^{31}$P can be used to study PMEs and PDEs involved in lipid metabolism. Brief summaries of $^{31}$P applications to brain and muscle are discussed in this section.

3.1.1 Phosphorus-31 Spectroscopic Imaging of the Brain

An early description of $^{31}$P spectroscopy imaging (SI) was provided by Maudsley and colleagues.$^{(7,51)}$ In their 1984 study, MRI techniques were applied to in vivo spectroscopic analysis of spatially resolved phosphorus spectra in the cat brain to determine whether changes associated with stroke could be detected. Two-dimensional images of separate phosphorus-containing compounds, as well as spectra arising from spatially localized points, demonstrated that metabolism within the tissue could be monitored in this manner. They also demonstrated preliminary results of phosphorus imaging of the human body in vivo.$^{(51)}$ Later, they were able to obtain $^{31}$P spectroscopic images at 3.5 cm spatial resolution in the human brain with times of 37 min at 2.0 T.$^{(52)}$ Sasahira et al. reported $^{31}$P-SI changes immediately after an ischemic insult, even though MRI and CT (computerized tomography) were negative.$^{(53)}$ Hubesch et al. reported $^{31}$P metabolite concentrations were significantly reduced in tumors, infarcts, and deep white matter lesions.$^{(54)}$

Three reports have demonstrated the feasibility of interleaving $^{31}$P and proton spectroscopic imaging.$^{(14,55,56)}$ This would be important because there is information that is mutually exclusive in both $^{31}$P and proton spectroscopy. Gonen et al. developed a $^{31}$P-SI technique that was a hybrid of two localized spectroscopy techniques, CSI and Hadamard spectroscopic imaging (HSI).$^{(57)}$ With this technique, they were able to shorten the acquisition time and also maintain intervoxel spectral isolation.$^{(57)}$ Gonen et al. also used a technique with polarization transfer from $^1$H to $^j$-coupled $^{31}$P, called refocused insensitive nucleus enhancement by polarization transfer (RINETP) and combined it with 3D CSI sequences on a clinical imager.$^{(58)}$ The technique was demonstrated on a phantom and in vivo human brain. Compared with direct $^{31}$P Ernst-angle excitation, signal gains of up to $\times1.8$ were obtained mainly as a result of spin–lattice relaxation time (T1) differences between $^{31}$P and $^1$H. Spectral interpretation was also simplified by editing out all non-proton-coupled $^{31}$P signals.$^{(58)}$ Example $^{31}$P-SI in the brain and the polarization transfer spectra are shown in Figure 2.

Jung et al. were able to measure the $j$-coupling constants of ATP in the brain using $^{31}$P-SI.$^{(59)}$ Both the $j$-coupling constants and the chemical-shift difference between $\alpha$-ATP and $\beta$-ATP were used to calculate the concentration of intracellular free magnesium in the brain.$^{(59)}$ A very recent report by Barker et al.$^{(43)}$ shows superb $^{31}$P multislice SI in the human brain at 3 T (most clinical MRI scanners have magnets of only 1.5 T). Images of free magnesium concentrations and pH as well as PMEs, PDEs, Pi, PCr, and ATP were calculated from the SI data.$^{(43)}$ An example of $^{31}$P metabolite images is shown in Figure 3.
In an effort to understand white matter MR signal hyperintensities in aging, Constans et al. used $^{31}$P-SI and $^1$H-SI. They demonstrated that white matter lesions were associated with increased signal from choline-containing metabolites, no significant change of signal from N-acetylaspartate, and a trend to a decreased PME resonance. Richardson et al. demonstrated an increased level of PME in the dyslexic brain compared to controls, using a four-dimensional SI technique. Deicken et al. used $^{31}$P-SI to demonstrate that schizophrenics had a significantly higher right relaxation times.

Volunteers with the corresponding ratios in patients with temporal lobe epilepsy. They were able to lateralize the seizure focus in temporal lobe epilepsy patients using various phosphorous metabolite ratios – PCr/Pi, PCr/$\gamma$-ATP, and $\gamma$-ATP/Pi – and to compare with clinical lateralization results. They found an average reduction of 15% in the PCr/Pi and $\gamma$-ATP/Pi ratios compared with the corresponding ratios in healthy volunteers in the mesial temporal lobe, and more than a 30% reduction in these two ratios in the anterior region of the epileptogenic mesial temporal lobe. The lateralization based on either the PCr/Pi or the $\gamma$-ATP/Pi ratio yielded a correspondence of 70–73% with the final clinical lateralization. Compared with the intracranial electroencephalogram (EEG), a 78% correspondence was found with the $^{31}$P-NMR-based lateralization, whereas MRI provided a correspondence of only 33%, and scalp EEG provided a correspondence of only 56%. These results suggest the utility of adding the $^{31}$P-NMR method to the group of noninvasive modalities used for presurgical decision-making in temporal lobe epilepsy patients. Other investigators have encouraging results for the use of $^{31}$P-SI in epilepsy.

### 3.1.2 Phosphorus-31 Spectroscopic Imaging of the Heart and Skeletal Muscle

Bottomley et al. have used $^{31}$P-MRSI in the heart to measure metabolite concentrations of PCr and ATP. Schaefer et al. used $^{31}$P-SI to measure abnormalities in patients with cardiomyopathy and left ventricular hypertrophy. Robitaille et al. were able to overcome surface coil rf field inhomogeneity artifacts using adiabatic pulses during $^{31}$P-SI of the canine heart. Auffermann et al. tested the concept that cine MRI and $^{31}$P-MR spectroscopy might be used to provide a comprehensive evaluation of the functional and metabolic status of the myocardium in humans. The result was that the ratios PDE/PCr and PDE/$\beta$-ATP were significantly higher in patients with dilated cardiomyopathy compared with healthy volunteers. They suggested that increased myocardial PDE might be a marker for abnormally low myocardium. Hetherington et al. used high-field (4 T) three-dimensional spectroscopic imaging (3DSI) to acquire PCr images of the human heart with 8 cc voxels. The PCr images enabled observation of the septum, left ventricular free wall, apex, and skeletal muscle. Quantitative evaluation of the 50 myocardial voxels acquired from 10 studies of healthy adults revealed a PCr/ATP ratio of 1.80 ± 0.32 after correction for saturation effects. An example of $^{31}$P-SI data of the heart is shown in Figures 4 and 5.

Campbell et al. used $^{31}$P-MRSI at 2 T to monitor high-energy phosphate metabolism over a 3-week period in a canine model of myocardial infarction and reperfusion.
A metabolic protective effect was observed (versus controls) with both nitroglycerin and superoxide dismutase, manifested by a reduction in the degree of pH decline from baseline values and preservation of the ATP/total phosphate ratio during occlusion and reperfusion. This was an excellent demonstration that \(^{31}\)P-SI can be used for the noninvasive assessment of myocardial metabolism in response to therapeutic intervention.\(^{(75)}\) This same group also measured the \(^{31}\)P metabolic effects during myocardial ischemia and sustained reperfusion of two other interventions (antianginal agents, diltiazem and propranolol).\(^{(76)}\)

Jeneson et al. used two-dimensional phosphorus chemical shift imaging (2D/\(^{31}\)P/CSI) to investigate macroscopic heterogeneity within the flexor digitorum profundus (FDP) muscle of the human forearm during exercise.\(^{(77)}\) They measured differences in Pi and PCr within the FDP in regions of active and inactive fibers during flexion of individual fingers. These results of this study demonstrate the potential of 2D/\(^{31}\)P/CSI for in vivo investigation of intramuscular heterogeneity in human skeletal muscle.\(^{(77)}\)

A similar study was performed by Kushmerick et al., where the distribution of muscle fiber types were measured by \(^{31}\)P-SI.\(^{(17)}\) The result was that the PCr/ATP and PCr/Pi ratios were significantly higher in the medial gastrocnemius and tibialis anterior muscles than those for the lateral gastrocnemius and soleus.\(^{(17)}\)

### 3.2 Carbon-13

The greatest advantage for carbon-13 spectroscopic imaging over protons and phosphorus is that a \(^{13}\)C-labeled chemical can be introduced into the biological system and both the metabolic incorporation and breakdown can be measured noninvasively in biochemical pathways...
such as in carbohydrate or lipid metabolism. This is possible because the natural occurrence of $^{13}$C is only 1% of the carbon nuclei which are mostly $^{12}$C (with no MR signal). It has the advantage over nuclear medicine techniques because not only can the presence of the label be spatially detected but also the chemical form of the label can be detected. Direct $^{13}$C-SI has much less signal-to-noise ratio than both $^1$H-SI and $^{31}$P-SI. However, there are some techniques that allow the carbon nuclei to be indirectly observed through the adjacent protons. Van Zijl et al. measured the metabolism of $[1-^{13}$C$]$-glucose in the cat brain using gradient-enhanced proton-detection heteronuclear spectroscopy.\(^{(78)}\) By observing the protons which were coupled to $^{13}$C nuclei, they were able to detect $[1-^{13}$C$]$-glucose, $[3-^{13}$C$]$-lactate, $[4-^{13}$C$]$-glutamine, $[4-^{13}$C$]$-glutamate and the combined signals $[2-^{13}$C$]$-glutamate/glutamine and $[3-^{13}$C$]$-glutamate/glutamine, despite the fact that some of the associated proton resonances were close to the water signal.\(^{(78)}\) Lee et al. proposed a scheme for acquiring $^{13}$C spectroscopic images using inverse detection via polarization transfer through protons and they experimentally verified the technique by a phantom using a heteronuclear multiple-quantum coherence technique.\(^{(79)}\) Using this scheme, they were able to gain signal and have an improvement of the time efficiency of data acquisition compared to the conventional 3DFT technique without sacrificing the most important attribute of $^{13}$C, the enormity of the chemical shifts.\(^{(79)}\)

Using direct detection of carbon-13, Hammer showed that proton-decoupled $^{13}$C images had an increase in sensitivity over nondecoupled $^{13}$C images because of the nuclear Overhauser effect (NOE) and elimination of multiple lines from scalar $^{13}$C-$^{1}$H spin–spin couplings.\(^{(80)}\) Morishita et al. used a CHESS pulse to image $^{13}$C-labeled glucose in the rat head at 7 T and at a spatial matrix size of $64 \times 64$.\(^{(81)}\) Beckmann et al. measured proton-decoupled $^{13}$C-NMR spectra of the human head during hyperglycemic glucose clamping using intravenous infusions of $[1-^{13}$C$]$-glucose in normal volunteers.\(^{(82)}\) The spatial localization of the different regions of interest was confirmed by $^{13}$C-NMR spectroscopic imaging with a time resolution of 9 min. They were able to measure the time course of metabolic breakdown products of $[1-^{13}$C$]$-glucose and also $^{13}$C-label incorporation into the C2, C3, and C4 resonances of glutamate/glutamine and into lactate in the human brain.\(^{(82)}\) Carbon-13 SI in combination with $^{13}$C labeled glucose makes it possible to obtain time-resolved, spatially selective, and chemically specific information from the human body.\(^{(82)}\) An example of $^{13}$C spatially resolved spectra from the human brain is shown in Figure 6. All of these results suggest the possibility of measuring spatially resolved chemical information from the human body that may have a clinical application for detecting metabolic disorders.

### 3.3 Fluorine-19

Fluorine MRI also has the advantage of no tissue background signal and the fluorine-containing compound has to be introduced from an external source. This section covers the applications of fluorine MRI to study anatomy, fluoro-deoxy-glucose metabolism, fluorine-containing anesthetics, tissue oxygen tension,
cerebral blood flow, and tumor metabolism of fluorine-containing anticancer drugs.

Schwarz et al. used $^{19}$F-MRI in conjunction with perfluorononane to develop a new technique for gastro-intestinal (GI) imaging. Due to the lack of $^{19}$F background signals, the contrast of the GI tract was only limited by the signal-to-noise ratio of the $^{19}$F-MR images. Fluorine-19 RARE (rapid acquisition with refocused echoes) images of 1-mm slices with an in-plane resolution of $0.23 \times 0.23$ mm$^2$ were obtained from the GI tract after oral perfluorononane administration. The passage of perfluorononane through the entire GI tract was monitored by repetitive MR measurements with a maximal time resolution of 38 s. The 3D surfaces of the GI tract were reconstructed and superimposed on corresponding $^1$H-MR images, which provided complementary anatomical information. Duong et al. used $^{19}$F-2-fluoro-2-deoxyglucose-6-phosphate (2FDG-6P) as a compartment-specific marker in normal and globally ischemic rat brain. Assuming that 2FDG-6P reflects water motion, this study showed that water ADC (apparent diffusion coefficient) decreases in both spaces after ischemia, with the reduction of intracellular water (intracellular compartment, which can be explained as retention of fluorouracil in hepatocytes). Aboagye et al. have demonstrated the feasibility of noninvasive MRSI and SI (CSI) to detect activation of the prodrug 5-fluorocytosine (5-FCy) to the cytotoxic species 5-fluorouracil (5-FU) by monoclonal antibody cytosine deaminase (CD) conjugates. Other investigators have also used $^{19}$F to measure oxygen tension. After pretreatment of H2981 tumor-bearing mice with L6-CD, in vivo metabolism of 5-FCyt to 5-FU within the tumors was detected by $^{19}$F-MRS; the chemical shift separation between 5-FCy and 5-FU resonances was approximately 1.2 ppm. Whole body $^{19}$F-CSI (6 x 6 mm in-plane resolution) of tumor-bearing mice demonstrated the highest signal intensity of 5-FU within the tumor region. This study supports further development of noninvasive MR methods for preclinical and clinical monitoring of CD enzyme-prodrug therapies.

Lee et al. proposed the use of $^{19}$F imaging combined with the relaxation enhancement of the gadolinium contrast agent Gd-DTPA. There is a linear relationship between the T1 relaxation rate of fluorine-19 of a perfluorochemical (PFC) and the partial pressure of the oxygen ($pO_2$) dissolved in the PFC. Tran et al. measured a linear relationship between the $^{19}$F T1 relaxation rate (1/T1) of the 3.5% w/v emulsion and dissolved $pO_2$ and determined the slope of 0.0033 s$^{-1}$/mm Hg$^{-1}$ and a correlation coefficient of 0.991. In vivo measurements indicated a 20 mm Hg increase in intracellular $pO_2$ of liver phagocytes when the inspired gas was changed from 20% to 100% $O_2$. Pratt et al. have also used a $^{19}$F imaging technique (in this case a 3D spatial technique) for mapping oxygen tension. Mason et al. developed a new technique for measuring tumor oxygen tension in vivo based on $^{19}$F-NMR spin–lattice echo-planar imaging (EPI) relaxometry of hexafluorobenzene (HFB). They were able to monitor dynamic changes in regional tumor oxygenation in response to respiratory challenge, and local $pO_2$ was determined using pulse burst saturation recovery $^{19}$F-NMR/EPI on the basis of the spin lattice relaxation rate. Following irradiation (20 Gy), tumor oxygenation was significantly elevated and remained high for at least 10 h. Brix et al. demonstrated simultaneous acquisition of $^{31}$P and $^{19}$F permits localized study of the influence of hepatic metabolism on the uptake and catabolism of fluoropyrimidine drugs. A well-known radiopharmaceutical 2-deoxy-2-fluoro-d-glucose (FDG) widely used for positron emission tomography diagnosis in terms of glucose utilization, has been evaluated as an NMR pharmaceutical for cancer detection. Kanazawa et al. studied the uptake and metabolism of FDG in the experimental tumor,
MH134, transplanted to the peritoneum of C3H mice as an ascitic tumor and measured the signal by $^{19}$F-NMR. In these tissues, the 6-phosphate of the injected compound was converted reversibly to its epimer 2-deoxy-2-fluoro-D-mannose (FDM) and further to their nucleoside diphosphate (NDP) bound forms. Through the use of in vivo $^{19}$F-NMR spectra and $^{19}$F-CSI, the $^{19}$F-NMR signal of NDP/FDM could be detected 1 day after the FDG injection and could be used as a target signal for tumor detection.

### 3.4 Multinuclear Single Resonance Imaging

There are several MR-detectable nuclei that do not require SI techniques for spatial mapping because they produce only one resonance. This section covers MRI of sodium, xenon, helium, and boron.

#### 3.4.1 Sodium Imaging

Sodium MRI has been investigated in medicine because of the importance of membrane integrity for maintaining different sodium concentrations in the intracellular and extracellular spaces in healthy tissue. The first in vivo NMR images of tissue sodium were shown by Hilal et al. They were able to measure an increase in the regional sodium NMR signal after brain infarction in an animal stroke model. Because sodium has a short T2 component, Ra et al. developed a technique for sodium imaging with a short echo time of 3.6 ms and this technique was used clinically for in vivo imaging of sodium-23 in the human head. In living tissues, sodium exhibits at least two transverse relaxation constants, namely a short component $T2s = 0.7–3.0$ ms and a long component $T2e = 16–30$ ms. Their imaging method combined both projection reconstruction and Fourier encoding schemes and they claim that when using the shorter echo time, there is an increase in the MR signal and improved visibility of intraparenchymal sodium. In another clinical study, Grodd and Klose noted that, in the brain, most of the sodium MR signal comes from the extracellular spaces such as the cerebral spinal fluid (CSF) spaces, whereas the normal parenchyma is not visible. Changes induced by encephalitis, ischemic infarction, and tumors were detected by the increased sodium signal in BSH. Bendel et al. have measured the longitudinal and transverse relaxation rates for the $^{11}$B resonances in BSH. These results were used as a basis for assessing the requirements and limitations of using $^{11}$B-NMR to determine BSH concentrations in vivo. Bendel et al. also used surface coil $^{11}$B-NMR spectroscopy of mice injected with BSH to demonstrate that the BSH MR signal was significantly higher in tumors, compared with muscle tissue, whereas the uptake and clearance kinetics were similar. Richards et al. used a gradient echo pulse sequence (echo time of 0.8 ms) to image boron-11 in rabbits injected with BSH. These studies show an important application of boron MRI that could be used in developing better pharmaceuticals for BNCT as well as for therapy planning during the clinical use of BNCT.

#### 3.4.3 Boron Imaging

Noninvasive techniques for mapping the spatial distribution of boron-containing compounds have been of interest for investigators of BNCT. Although the $^{10}$B isotope is the form used with BNCT, $^{11}$B-MR has higher signal-to-noise than $^{10}$B-MR and can be used to map the spatial distribution. The compound Na$_2$B$_2$H$_4$SH (BSH) has been suggested for BNCT of glioblastoma multiforme. Bradshaw et al. used a 3DPR method to obtain in vivo $^{11}$B images in a large canine brain tumor model and in a human infused with BSH. The 3DPR method demonstrates a signal-to-noise ratio that allows qualitative kinetic studies of the boron compound in normal and in tumor tissue of the head. They were able to obtain human boron images from a patient who underwent surgical resection and volumetric debulking of a large (7 cm) glioblastoma multiforme after BSH injection. Bendel et al. have measured the longitudinal and transverse relaxation rates for the $^{11}$B resonances in BSH. These results were used as a basis for assessing the requirements and limitations of using $^{11}$B-NMR to determine BSH concentrations in vivo. Bendel et al. also used surface coil $^{11}$B-NMR spectroscopy of mice injected with BSH to demonstrate that the BSH MR signal was significantly higher in tumors, compared with muscle tissue, whereas the uptake and clearance kinetics were similar. Richards et al. used a gradient echo pulse sequence (echo time of 0.8 ms) to image boron-11 in rabbits injected with BSH. These studies show an important application of boron MRI that could be used in developing better pharmaceuticals for BNCT as well as for therapy planning during the clinical use of BNCT.

### 4 SUMMARY AND CONCLUSIONS

This article has discussed several MRSI techniques and applications for several different nuclei. Spectroscopic
imaging allows biomedical scientists and clinicians to map chemicals in the body noninvasively. There are important medical applications of MRSI that involve measuring the change in detectable biochemicals during a physiological perturbation or detecting a change in biochemicals, compared to normal controls, caused by diseases such as cancer or neurological disorders. This technique is suitable for detecting low-molecular-weight chemicals such as ATP or lactate, but is not suitable for directly detecting large-molecular-weight chemicals or chemicals in the solid state such as DNA, enzymes, or bone.

In vivo near-infrared (NIR) spectroscopy has the potential of becoming an important tool in a number of areas in clinical medicine. Technological developments in photonics that have been spurred on by the communication revolution have set the stage for rapid advancement of optical and NIR spectroscopy based on noninvasive or minimally invasive medical diagnostic techniques. The goal of this article is to review the current capabilities and limitations of in vivo NIR spectroscopy and highlight the impact of these capabilities and limitations in selected areas where NIR spectroscopy is being used to address clinical problems. The optical properties of tissues are briefly reviewed, as are the instrumental methods available to the experimentalist. These properties and methods largely dictate the feasibility of an in vivo spectroscopic diagnostic approach and constrain the scope of problems that can be tackled using optical–NIR spectroscopy. Some of the more successful applications are described, including studies of tissue oxygenation, ischemia, and viability. A number of factors that can confound interpretation of in vivo NIR results are discussed. The number and magnitude of confounding influences that arise in in vivo spectroscopy can be daunting to the experimentalist and may represent the largest barrier in transforming in vivo spectroscopic measurements into clinically meaningful and reliable information. In vivo NIR spectroscopy abounds with opportunity and challenge.

1 INTRODUCTION

In vivo NIR spectroscopy involves analyzing the wavelength dependence of the attenuation of NIR light by living tissue, in situ. This is accomplished by measuring the light between the red end of the visible (600 nm) to the long wavelength NIR (2500 nm) of the electromagnetic spectrum that is diffusely reflected by the tissue and/or transmitted through the tissue. The attenuation of light by tissue is governed by both the light absorption properties and scattering characteristics of the tissue. Scattering is largely dictated by the structural properties of tissue such as boundaries and interfaces, cell count, particle size and shape. The light absorption characteristics of tissue are determined by the types and concentrations of constituent chromophore biomolecules. It is perhaps the complexity of the dynamic matrix of living tissue and the strong interplay between absorption and scatter-related contributions to the attenuation of NIR light by tissue that are the distinguishing elements of in vivo NIR spectroscopy. Despite the complexity, in vivo spectroscopy shares common goals with optical and infrared (IR) spectroscopic techniques applied to better defined and more ordered systems. The aims of most spectroscopic studies on tissues are to identify chromophores present in the sample, perform quantitative and/or semiquantitative analysis on the chromophores present, and correlate changes in the bulk optical properties of the tissue to morphological or structural changes in the tissue. While this information is, in principal, latent in the NIR attenuation spectrum of tissue, the extraction of this information and its translation into medically relevant findings presents a major challenge in the analysis of in vivo NIR spectra.

The prospects for in vivo NIR spectroscopy are appealing and the stage is set for rapid advancement
of noninvasive or minimally invasive optical and NIR spectroscopy based solutions to medical diagnostic problems. This prognosis is borne out by the explosion of recent developments in this area. This article is intended to highlight the current capabilities and limitations of in vivo NIR spectroscopy, provide a brief discussion of the more active application areas of the technology as well as a selected view of the recent literature. Finally, we will speculate on future developments and applications.

2 OPTICAL PROPERTIES OF LIVING TISSUES

2.1 Background

The continuous measurement of metabolic, physiological, or structural changes in tissue is of primary concern in many clinical and biomedical domains. Biochemical or physiological changes in the body are usually accompanied by medical problems. These changes lead to microscopic structural and chemical alterations that can influence morphology and function, creating symptoms that are clinically identifiable. The challenge for medical diagnostic techniques is to detect tissue changes at an earlier stage so that therapeutic interventions may have the greatest impact on the disease or problem.

Classical methods of in vivo assessment or diagnosis are either invasive, requiring a sample for histological examination\(^{(1)}\) or the insertion of an electrochemical probe\(^{(2)}\) or they use ionizing radiation\(^{(3)}\). The increasing reliance on magnetic resonance imaging methods with the subsequent displacement of some traditional nuclear medicine techniques and X-ray based methods indicate the recent move toward methods that are less invasive and subject the patient to lower energy or lower radiation doses. An alternative approach to these techniques uses NIR light to probe tissue in a noninvasive manner. The NIR region of the electromagnetic spectrum is composed of wavelengths ranging from 700 to 2500 nm and has previously been used to measure hemoglobin (Hb)\(^{(4-6)}\), myoglobin\(^{(7,8)}\), cytochrome \(aa_3\)\(^{(9-11)}\), and water\(^{(12-14)}\) in tissues. The NIR spectra of some of these chromophores are depicted in Figure 1. The spectral region between 700 and 1300 nm has special significance in biomedical applications with respect to photodynamic therapy\(^{(15)}\) and dosimetry\(^{(16)}\). The NIR region involves the study of high-energy vibrational transitions and low-energy electronic transitions. Many of the absorptions in this region result from overtones and combinations of fundamental mid-IR molecular stretching and bending vibrations\(^{(17)}\).

The prominent overtone absorptions observed in the NIR

\[ A_\lambda = -\ln \left( \frac{I_o}{I_{\lambda o}} \right) = \varepsilon_\lambda bc \]  

where \(\varepsilon_\lambda\) (cm\(^{-1}\) M\(^{-1}\)) is the wavelength-dependent extinction coefficient, \(b\) (cm) the sample thickness, and \(c\) (M) the concentration of chromophore in the medium. For a given chromophore, the extinction coefficients vary with wavelength, thus producing a wavelength-dependent spectrum. To simplify the relationship in tissue studies, the absorptivity and concentration terms are combined into a single parameter, the absorption coefficient defined as \(\mu_a = \varepsilon c = A/b\) (cm\(^{-1}\)). The absorption coefficient describes the concentration of the chromophore in relation to the absorbance per unit length through the sample. Multiwavelength transmittance measurements using Equation (1) are applied to a variety of scatter-free solutions in routine clinical analysis. However, tissue chromophores are generally situated in a turbid or scattering media. An example of this is Hb in tissue.

Quantitative analyses in turbid media are difficult because of the spectral aberrations associated with multiple scattering events. When light strikes a sample containing scatterers, the light travels a distance greater
than the sample thickness as a result of the multiple scattering. Therefore, the Beer–Lambert relationship fails in a scattering medium since the actual pathlength is greater than the sample thickness. Scattering disperses the light in all directions, hence a small fraction of the scattered light that penetrates into the sample can be remitted back out to the surface. The remitted or diffusely reflected light collected by the detector has been attenuated as a result of the scattering as well as through absorption by the chromophores in the tissue. A measure of the reflected light provides spectral information on the scattering by the tissue and absorption by the tissue chromophores. Reflectance measurements rely on the sample containing scatterers to reflect the light back to the tissue surface. The type and direction of the scattering is strongly influenced by the size, shape and density of scattering particles present in the tissue. Absorption changes are easily measured provided the scattering properties of the tissue remain relatively constant throughout the observation. However, this condition is often violated when spectroscopic measurements are made on dynamic living tissue.

2.2 Tissue Absorption

Compared to the shorter ultraviolet (UV) and visible wavelength regions as well as the longer mid-IR wavelength range, the NIR wavelength range is ideally suited for in vivo tissue spectroscopy. This suitability stems from the absorption and scattering properties of tissue in the NIR. In the NIR range, the absorption by tissue chromophores is small in comparison to the mid-IR, visible and UV ranges. Although weaker tissue absorption in the NIR implies that less information is available spectroscopically, NIR light can traverse a greater distance in tissue before it is completely attenuated by chromophore absorption. This greater penetration depth of NIR light into tissue lies at the heart of its clinical utility. Whereas only the upper 10–20 µm of tissue are interrogated by mid-IR light before being completely absorbed, depths of several centimeters can be sampled in tissue using NIR light. This extended sampling depth increases the number of potential in vivo clinical applications of NIR spectroscopy relative to UV, visible and mid-IR spectroscopy. However, the weak absorption characteristics of tissue which enable deeper light penetration ultimately limit the sensitivity and type of information that can be retrieved using NIR spectroscopy.

The most clinically relevant tissue chromophores in the NIR are oxy- and deoxyhemoglobin, oxy- and deoxymyoglobin, oxidized and reduced cytochrome aa₃, and water. These chromophores provide vital tissue information related to oxygen delivery, storage, utilization, and tissue hydration.

Hb is often considered to be a respiratory pigment contained within red blood cells. One red blood cell contains approximately 265 million molecules of Hb. Hb is an iron-containing protein composed of polypeptide chains. The oxygenated (HbO₂) and deoxygenated (Hb) forms have different extinction coefficients across the visible and short wavelength NIR regions, as seen in Figure 2. In the visible portion of the spectrum, HbO₂ has two peaks centered at 540 nm and 576 nm, whereas Hb has only one peak at 555 nm. Although the human body is robust in many respects, the physiological process of maintaining proper oxygen transport is a delicate and complex system. The relative oxygen saturation (O₂sat), a measure of the relative amount of oxygenated Hb to the total amount of Hb present (defined as \(O₂_sat = [HbO₂]/([HbO₂] + [Hb])\)), provides a quantifiable measure of the oxygen transport in tissue. Using an unknown tissue spectrum and two or more of the extinction coefficients for oxy- and deoxyhemoglobin, the O₂sat for tissue can be determined.

Although the maximum extinction coefficients for HbO₂ and Hb lie in the visible portion of the spectrum, these values are not typically used for in vivo applications due to the presence of interfering chromophores in skin. For most in vivo NIR applications, spectra are obtained through the surface of the skin (transcutaneous). The major absorption in skin in the visible wavelength range results from melanin, a complex absorbing pigment found in the epidermal layer of the skin. Melanin is a highly effective absorber of light, especially in the UV region.
of the spectrum. The absorption of light by melanin in the UV and visible regions directly affects the reflected and transmitted light through skin. However, in the NIR spectral region, the absorption from melanin is minimal while Hb and myoglobin are the dominant absorbers in the short wavelength NIR region (650–900 nm). Several methodologies have been used to determine the O$_2$sat in tissue employing the NIR wavelength region.$^{(19)}$

The most common tissue chromophores found in muscle are Hb, myoglobin, cytochrome and water. Blood contains Hb, which carries oxygen to the tissue, where it is stored by myoglobin. Oxy- and deoxymyoglobin have distinct absorption spectra in the NIR.$^{(20)}$ To determine the oxygen saturation in muscle, i.e. the amount of oxygen present in muscle tissue in relation to the maximum storage capacity, the optical properties of myoglobin can be exploited in a similar manner to Hb by determining the myoglobin oxygen saturation. This parameter can be obtained by measuring the absorbed light at two or more different wavelengths, namely the oxy- and deoxy- absorption bands, and the oxygen saturation is calculated via a ratio of the oxy- absorption to the total oxy- and deoxy- absorptions.$^{(20)}$ Noninvasive quantification of intracellular oxygenation in muscle is useful in determining the physio-pathological state of patients in such applied areas as sports medicine or physiotherapy. In vivo NIR spectroscopy of myoglobin represents one step towards fully understanding the respiratory chain. Unfortunately, the visible–NIR absorption spectra of Hb and myoglobin are not easily distinguished. Therefore in blood perfused muscle, NIR oxygen saturation measurements represent the extent of both Hb and myoglobin oxygenation in the muscle.

Hb and myoglobin oxygenation measurements yield useful information about oxygen delivery and utilization. In some ways, the intracellular oxygen content can be inferred based on these measurements. A direct approach using cytochrome oxidase measurements is often preferred to determine intracellular oxygen content and utilization. Intracellular oxygen content, specifically oxygen consumption, is of primary importance in understanding physiology and pathophysiology when dealing with cellular neural damage,$^{(21)}$ cerebral activity,$^{(22)}$ and detection of hematomas$^{(23)}$ since proper brain function is highly dependent on oxygen content. Oxygen metabolism at the cellular level occurs at the mitochondria in the presence of cytochrome oxidase. Cytochrome oxidase is the terminal enzyme in the cellular respiratory chain located within the membrane of the mitochondria. The enzyme contains four redox active centers that change oxidation state during electron turnover of the enzyme. Oxygen consumption in tissue involves the transfer of electrons from the redox active centers to the oxygen. The transfer of the four electrons to oxygen and the subsequent reaction with cellular matter results in the production of four hydrogen ions, which leads to the formation of water. In the NIR region, the reduced and oxidized states of the Cu$_b$ copper center of cytochrome oxidase have weak absorption bands.$^{(9)}$ In the oxidized state, cytochrome oxidase has a weak broad absorption band between 700 and 900 nm centered at 830 nm. This broad absorption band is de-emphasized in the reduced state of the enzyme. Since the total concentration of cytochrome oxidase does not change during oxidative phosphorylation, spectral measurements of the enzyme reflect the relative concentration of the oxidized and reduced species. As such, simply observing the spectral difference between the oxidized and reduced forms of the enzyme allows for concentration measurements of the intracellular oxygen consumption to be determined. The spectral difference in the oxidized and reduced forms of the enzyme is shown in Figure 1. Since the flux of reducing equivalents into the cytochrome electron transport chain is regulated by the rate of adenosine triphosphate hydrolysis or work, the application of NIR to detect the redox balance of cytochrome oxidase can provide a noninvasive method to monitor oxygen consumption and activity at a cellular level.

Although the extinction coefficients for cytochrome are similar in magnitude to Hb, as seen in Figure 1, cytochrome quantitation using the NIR is difficult. In general, the concentration of cytochrome oxidase is approximately one tenth the Hb concentration in most tissue.$^{(24)}$ Substantial work has been done to interpret NIR spectra and extract the cytochrome signal from the strong Hb absorption, with limited success.$^{(19)}$ Reliable qualitative measurement of the oxidation and reduction of the Cu$_b$ copper metal center of cytochrome $c$ oxidase using NIR spectroscopy remains an active and hotly contested area in in vivo spectroscopy.

The human body is composed of approximately two-thirds water. Although the majority of the water is contained within cells, approximately 8% is present in the bloodstream. In the NIR wavelength region of tissue spectra, the strongest absorption is due to the O–H water absorptions. The water spectrum in the NIR region, as shown in Figure 3, contains a strong combination band at 1940 nm, the first overtone of the O–H stretching vibration at 1440 nm, a weaker combination band at 1200 nm and second and third overtone vibrations at 980 and 740 nm.$^{(25)}$ Light absorption by tissue is mainly due to the water present in tissue, therefore making the NIR spectral region ideal for studying the properties of water in tissue. Water and its temperature dependent spectral variation has been a field of interest in biomedical tissue spectroscopy. The extinction coefficients of water are extremely temperature dependent, such that a
temperature variation will cause a spectral shift in the NIR spectrum. A temperature increase from 37°C to 41°C will cause the water spectrum to shift to shorter wavelengths (a hypsochromic shift). Therefore, one application of the water absorption band is as a noninvasive temperature monitoring system. Since the absorption of light is proportional to the chromophore content present in tissue, NIR can be used to determine quantitative and qualitative in vivo tissue hydration. In some clinical measurements, water is assumed constant and can be used as a fixed constant absorber or internal standard to correct for pathlength variations arising from tissue scattering. Assuming the water content in tissue is known, the absorption observed is in direct proportion to the optical pathlength traveled by the light in the tissue. Scattering and absorption at the water wavelength is assumed to be representative of those occurring at other wavelengths in the sample. However, this method is often difficult to implement since the water absorption may not reside in the same spectral region as the chromophore of interest and absorption from other chromophores in the tissue may also occur at the water wavelength. The limit in obtaining absolute quantitation in vivo NIR spectroscopy originates from the multiple scattering of light within tissue resulting in an unknown pathlength and chromophore absorption.

2.3 Tissue Scattering

Absorption of light by a sample in a nonscattering medium provides a quantitative assay of the analyte present. However, the transport of light through complex samples such as tissues is governed by the light-scattering interactions in the medium. Scattering of light occurs as a direct result of the interaction of light with random variations in the refractive index or small particles in the medium, resulting in a dispersion of the light in all directions. In particular, scattering within tissue results from microscopic and macroscopic constituents such as cellular membranes, refractive index mismatching between intra- and extracellular fluids, mitochondria, ribosome and fat globules. Particles smaller than the wavelength of the incident light can scatter radiation elastically without a change in energy. Small particle scattering in which the scattering occurs in all directions is called Rayleigh scattering. Rayleigh was the first to investigate from a theoretical standpoint the dependence of the scattered radiation intensity on the incident wavelength. In many quantitative analyses related to tissue, scattering has attributes which resemble scattering patterns described by Mie scattering. Mie scattering is associated with scattering when the diameter of the particles is not much smaller than the incident wavelength. Derivable from Maxwell’s equation, Mie scattering is a rigorous solution to the angular dependence of scattering for an arbitrary direction. However, both Rayleigh and Mie scattering provide only an approximate estimate of the wavelength-dependent scattering that occurs in tissue. The theories do not take into account multiple scattering or the presence of other nearby particles, an effect that becomes important for scattering in tissue.

When tissue is illuminated with NIR light, some of the light is absorbed by the tissue while a large portion of the light is diffusely scattered. The absorption coefficient, represented by $\mu_a$, indicates the frequency of absorption events per unit length traveled. In tissue, absorption by chromophores is small, with typical values in the NIR ranging between 0.1 and 10 cm$^{-1}$. The scattering coefficient, $\mu_s$, represents the frequency of scattering events per unit length traveled and ranges from 100 to 1000 cm$^{-1}$ in tissue, approximately two orders of magnitude greater than absorption. The combined attributes of low absorption and high scattering in tissue allow for the light to penetrate deep within tissue, approximately 1–10 cm$^{31}$ enabling extraction of deep tissue information noninvasively. The high remittance of the scattered light makes the NIR ideal for studying biological and physiological characteristics. The penetration depth into tissue is dependent on the type of scattering, more specifically, the direction in which the scattered photons travel.

A single photon entering a tissue sample will experience many scattering events as it propagates through the medium. When light interacts with multiple scatterers, the light is altered from its original direction. These interactions of light with tissue are highly forward directed, i.e. light propagates in a forward direction. Scattered photons can be described by a scatter probability distribution function $P(\theta)$, where $\theta$ is the scattered
photon angle after the interaction with a single scattering event. Phase distributions describe the scattering angle probability of the deflected light. The mean cosine angle of the phase distribution is used to describe the anisotropy of the scattered photon. This parameter, designated g, is called the anisotropy coefficient with values ranging from -1 (a totally back-scattered event) to 1 (a totally forward-scattering event). Isotropic scattering, g = 0, refers to a uniformly distributed scattering in all directions. Typical values of g for tissue in the NIR wavelength region range from 0.65 to 0.95. The scattering anisotropy can be combined with the scattering coefficient to produce a single term, the reduced scattering coefficient. Reduced scattering coefficients can be regarded as an effective isotropic scattering coefficient that represents the cumulative effect of several forward-scattering events. This reduced scattering coefficient parameter has special significance with respect to photon diffusion theory.

A photon traveling through a tissue sample may experience varying degrees of scattering, resulting in long paths through the tissue sample. Therefore, one effect of scattering is to increase the pathlength traveled by the photon, thus increasing the absorption of the light by chromophores. Either photon time or frequency resolved techniques can obtain the distribution or mean paths a photon travels through a given scattering sample. A representative diagram of both techniques is shown in Figure 4. Photon time-of-flight methods, a time resolved technique, use short pulses of illumination (<50 ps) in which the light is diffusely scattered in the sample. Semiconductor, dye, or solid state lasers produce the ultrashort pulses at discrete wavelengths in time-of-flight instruments. The output pulses from the laser are split in two by a beamsplitter in which a fraction of the light enters into a reference detector and the remaining pulse is directed into the tissue sample and ultimately to a response detector. The reference and/or response detectors used with time correlated photon counting instruments are photomultiplier tubes (PMTs), microchannel plate-PMT, avalanche photodetector, and streak cameras. The time difference between the reference and response detectors is directly related to the time the photon spent in the tissue sample. Electronics are used to digitize and collect the output response for a single photon event or photon path through the tissue. Using a large number of photons, an intensity distribution is constructed of the sum of the number of photons with various times through the sample. A measurement of the photon time distribution effectively probes a series of pathlengths through the sample. In general, the light measured in a scattering sample has traveled considerably further than the direct distance between the input and output sources. The mean time, \( \langle t \rangle \), corresponds to the center of mass of the photon time distributions as demonstrated in Figure 4(a). In essence, the detected photon distributions consist of the input response convolved with the absorption and scattering response from the tissue. Several methods exist to extract the chromophore concentration and scattering from the measured photon distribution.

Frequency domain or intensity modulated instruments also use a laser as a source except the intensity is modulated at radio frequencies with measurements of the intensity and phase made through the tissue sample. Small phase lag detection at radio frequencies are difficult, so practically all frequency resolved instruments employ a down-conversion scheme to bring the radio frequency signal down to intermediate frequencies where conventional phase detection methods can be applied. Knowledge of the phase shift and the modulation frequency can be used to determine the mean photon pathlength through the tissue sample. Applying this

![Figure 4](image-url)
modified or corrected pathlength into the Beer–Lambert relationship permits the determination of chromophore concentrations in a scattering medium such as tissue.

3 INSTRUMENTAL METHODS

Discovery of IR radiation can be traced to an experiment undertaken by William Herschel in 1800. Herschel carried out a simple experiment to satisfy his curiosity as to which color within the visible spectrum was responsible for heat in sunlight. The experiment consisted of measuring the temperature from one color to the next using a thermometer and a glass prism to separate the colors of the sun’s “white” light. Nothing was observed until the thermometer was positioned below the red end of the spectrum. At that point a temperature change indicated energy was present beyond the red light. Because Herschel could not see that light, he named it IR, using the Latin prefix “infra” meaning below. William Herschel is credited for the discovery of the IR region and is often known as the “father” of NIR spectroscopy.

Contemporary NIR instruments have vastly improved from Herschel’s initial experiment. NIR instruments can be used to measure tissue optical properties in vivo. These instruments can be classified as either broadband or discrete wavelength instruments, based on the wavelength selection method used.

3.1 Broadband Spectroscopy

Broadband spectroscopy refers to methods that observe the continuous spectral absorbance characteristics of a given sample within a given region of the electromagnetic spectrum (UV, visible, NIR, etc.). NIR broadband instruments for in vivo applications consist of three main components: a light source, a wavelength dispersing element, and a detection system. Light sources for broadband spectroscopy emit a wide spectral distribution of radiation. The most common light source for the NIR is the glass-encapsulated tungsten filament lamp. These sources provide radiation over the 400–2500 nm wavelength range being limited by the transmission characteristics of the glass. For samples requiring slightly higher light intensities than the tungsten lamp a quartz tungsten halogen lamp is available. Quartz tungsten halogen sources typically run at high temperatures thus producing high light throughputs. However, these sources tend to be less stable than normal tungsten lamps unless proper stabilizing electronics are incorporated into the lamp power supply.

Based on how wavelength selection is made, broadband NIR instruments can be classified as either dispersive or interferometric instruments. Dispersive wavelength selectors are the most commonly used, spatially spreading the light into its respective wavelengths using either prisms or diffraction gratings. Prisms separate the wavelengths spatially based on the wavelength dependence of the refractive index of the prism material. Light striking a prism is dispersed or separated in a nonlinear fashion such that shorter wavelengths (UV) are highly dispersed, while the longer wavelengths (NIR region) are less dispersed. Gratings, on the other hand, disperse the light into its wavelength components based on light diffraction and constructive wavelength interference rather than the variation in refractive index with wavelength. A diffraction grating is a plane or concave surface with ruled parallel, equally spaced grooves. Some of the basic designs of dispersive instruments are shown in Figure 5. Depicted in Figure 5(a) is the Bunsen design, used in early prism instruments. It uses two lenses and a prism for the wavelength selection. The separated wavelengths, illustrated as \( \lambda_1 \) and \( \lambda_2 \), are positioned on a single element detector by rotating the prism. Likewise, the Czerny–Turner design, depicted in Figure 5(b), requires the grating to rotate for wavelength
selection into the detector. Typical single element detectors used in the NIR region are PMTs and semiconductor based Si (360–1000 nm), PbS (900–2600 nm), InSb (1000–5000 nm), PtSi (1000–5000 nm) and InGaAs (1000–3000 nm). Prisms were commonly used in earlier NIR instruments for wavelength selection; however, recent instruments employ a grating design. Gratings offer a higher linear dispersion than prisms, typically tens of nanometers per millimeter. Holographic gratings have replaced mechanically grooved gratings. These have fewer defects, are easier to manufacture and have virtually perfect groove patterns. Additionally, modern instruments that incorporate gratings have a greater throughput across the entire NIR region.

Both the prism and grating designs of Figure 5(a) and (b) require lenses and/or mirrors to direct the light to the dispersive element. Wavelength selection is achieved by rotating the dispersion element. Optical components such as the mirror, lenses, and mechanical motion contribute noise and reduce instrument reproducibility. To circumvent these problems a “nonmoving part” dispersive instrument has been designed incorporating all the optical components into one system, as shown in Figure 5(c). The spectragraph of Figure 5(c) employs a concave holographic grating for both the dispersive and focusing elements, reducing the need for optical components, thus increasing the light throughput and reducing stray light within the instrument cavity. In place of the single element detector for single wavelength detection, modern dispersive instruments employ solid-state array detectors. These detectors consist of an array of a large number of closely packed miniature photoelectric semiconductor detectors. The detectors are either photodiode array or charge-coupled devices (CCDs). CCDS are solid-state sensors where the photon energy is converted and stored in a metal-oxide semiconductor. The greatest advantage of the array detectors is the immediate acquisition of the spectral response with readout times in the millisecond range. Since these detectors have multiple sensors, a rotating dispersive element is no longer necessary.

Interferometers are a class of instruments employing nondispersive devices in which the constructive and destructive interference of the light is exploited to obtain spectral information. Interferometers observe all optical frequencies from the source in a simultaneous and nondispersive manner. A classic example of an interferometer is the Michelson interferometer depicted in Figure 6(a). The instrument consists of several mirrors, a HeNe laser, photodiode detector, a beam splitter, and a NIR detector. Light from the source is split into two portions by the beam splitter. Half of the beam traverses the beam splitter and strikes a fixed mirror, while the remaining light is reflected to a moving mirror. When the mirrors are equidistant from the beam splitter i.e. no displacement, all wavelengths interfere constructively. Zero displacement is depicted as the large centered spike in Figure 6(b). As the mirror moves about this zero position, some of the wavelengths will constructively and destructively interfere. The degree of constructive/destructive interference is dependent on the mirror displacement and the wavelength of the incident radiation. The detected signal intensity versus the mirror displacement is known as an interferogram. In conjunction with the polychromatic

Figure 6 A typical Michelson interferometer. (a) General arrangement of the optical components of the Michelson interferometer. The interferometer produces an interferogram response illustrated in (b) for polychromatic light. Monochromatic light from a laser diode produces the response seen in (c). (d) Fourier transform of the interferogram to create the spectral response in the wavelength domain.
source, a monochromatic laser reference source follows a similar path through the interferometer mirrors. Since the laser is monochromatic, constructive/destructive interference from the laser produces bright and dark fields on the photodiode detector. The detector response for a monochromatic source is demonstrated in Figure 6(c). A dark field occurs when the moving mirror is placed \( \lambda/4 \pm n\lambda/2 \) \((n = 0, 1, 2, 3 \ldots)\) away from the zeroth position. The detected intensity and mirror displacement for a monochromatic source is related to the wavelength by a cosine function, \( \cos(4\pi x/\lambda) \). Polychromatic light consists of several wavelengths, each wavelength following a different cosine relation to produce constructive/destructive interference. The detected intensity for a polychromatic source is the sum of all the constructive/destructive interference from the various wavelengths emitted by the source. Shown in Figure 6(b) is a typical interferometric response for a polychromatic source. A Fourier integral can describe the intensity detected versus mirror displacement. Therefore, using the Fourier transform on the interferogram produces the spectral response in the wavelength domain as demonstrated in Figure 6(d).

The two greatest advantages of an interferometric instrument are the high spectral resolution that can be obtained at a fairly high signal-to-noise ratio (S/N) and the large light throughput. The improved S/N, in comparison to a dispersive single element detector, results from the multiplex advantage (Fellget’s Advantage) of interferometric instruments. Interferometers permit many wavelengths to be observed simultaneously since the detector is exposed to all wavelengths during the scan process. To demonstrate this multiplexed advantage, a simple S/N comparison can be made with a dispersive single element detector scanning instrument. For the S/N comparison, both interferometer and scanning instruments are assumed to cover the same number of \( m \) wavelength points at comparable resolution and time. Since spectra are taken over a constant time interval, the number of photons observed with the interferometer instrument is \( m \) times more than the scanning system. Thus, the S/N improvement in the interferometer is a factor of \( m^{1/2} \) better than the scanning instrument. Therefore, the multiplex advantage of interferometers occurs in situations where the detector noise is the limiting factor and signal averaging is necessary. Since interferometers have no entrance slits, the light throughput (Jacquinot’s advantage) is significantly larger than dispersive instruments. The throughput can often be a factor of 10 to 100 times more than conventional dispersive instruments.

### 3.2 Discrete Wavelengths

Discrete wavelength spectroscopy is the simplest method to make in vivo tissue measurements. Many in vivo NIR commercial instruments incorporate filters or diode lasers to measure the status of living tissue. The most well known discrete wavelength instrument is the pulse oximeter, designed to measure the relative tissue oxygen content. Millikan was one of the first people to measure Hb/myoglobin oxygenation with the use of two filters in the green and yellow wavelength regions.\(^{(41)}\) The filter wavelengths corresponded to the wavelength absorption of the oxygenated and deoxygenated forms of the chromophores. Spectroscopic instruments that employ filters for wavelength selection are typically referred to as spectrophotometers or photometers. Interference filters are the most commonly used method for discrete wavelength selection. Interference filters share some characteristics with interferometric methods employing destructive and constructive interference for wavelength selection. Interference filters are constructed in such a manner that when light strikes the filter, most of the light interferes destructively while a small band of wavelengths interfere constructively and pass through the filter. Depending on the filter design, the selected wavelength band can be wide covering a large wavelength range or extremely narrow (ca. 10 nm band).

The light sources of choice for discrete wavelengths when a narrow bandwidth is required are light emitting diodes (LEDs) and laser diodes. These sources are optoelectronic semiconductor devices that produce monochromatic light by electroluminescence. The material usually consists of GaAsP and GaP for wavelengths in the 380–800 nm range and GaAs for those beyond 800 nm. Oximetry is a prime example of the application of LED and laser diodes to determine blood oxygenation.\(^{(42)}\) The application of discrete wavelengths to in vivo spectroscopy relies on prior knowledge of the spectral characteristics of the chromophore of interest. The choice of wavelengths to use for a particular application cannot be made arbitrarily and must be made based on the extinction coefficients of the chromophore. For example, in pulse oximetry the choice of wavelengths is based on the absorption coefficients of the oxygenated and deoxygenated species of Hb, as demonstrated in Figure 7. The absorbances measured at 660 nm and 940 nm are predominately due to the deoxygenated and oxygenated Hb, respectively. The appeal of semiconductor sources lies mainly in the narrow spectral bandwidth achievable (<7 nm), small package size (~5 mm × 5 mm), and large radiant output. However, the discrete wavelengths available are somewhat limited, which often leads to a less than optimal in vivo measurement.

Liquid crystal tunable filters (LCTFs) are an ideal discrete wavelength selection instrument with narrow bandwidths (5–50 nm bandwidths) tunable over a broad wavelength range (400–1100 nm). LCTFs are electronically controlled interference filters that exploit the
localized to a distinct spot (1-cm diameter) on the tissue. The information acquired is discrete instruments is carried out at a single point on in vivo tissue sample. The information acquired is discrete instruments is carried out at a single point on the tissue sample.

In general, NIR spectroscopy using either broadband or discrete instruments is carried out at a single point on the tissue sample. The information acquired is localized to a distinct spot (1-cm diameter) on the tissue. Often this single point measurement is used to infer the regional health status of the tissue. However, there are clinical situations in which several such locations must be probed and assessed. Acquiring point spectroscopy at multiple locations introduces confounding variations and inaccuracies. Several methodologies have been developed to circumvent the limits of point spectroscopy, in particular, in vivo spectroscopic imaging. In vivo imaging requires a noninvasive method to collect pictures of the tissue at selected wavelengths. To add an imaging component to Fourier transform spectrometers, the interferometer has been modified to an imaging system incorporating a two-dimensional array at the image focal plane. The revised instrument permits the simultaneous collection of multiple spectra at multiple locations within the tissue sample. However, Fourier transform imaging spectrometers are generally limited to in vitro tissue samples.

CCDs, invented in 1970 by Boyle and Smith, are the most well known and used of the array detectors. These detectors convert light or photons into an electrical charge that is collected and stored in a metal oxide semiconductor. The accumulated charge is a linear function of the incident and exposure time to the radiation. The CCD response represents the reflected spatial light intensity of a given object. In the scientific realm, CCDs are most often used for the detection of weak signals or sources. Unlike conventional CCD, scientific grade CCDs have a lower dark noise, higher responsivity, a larger dynamic range and higher resolution. The operating spectral range of a typical CCD detector is between 400 and 1100 nm. However, a CCD detector for in vivo spectroscopic applications is of little use without some means of wavelength selection. Filters, the simplest form of wavelength selection, are often used in conjunction with CCD detectors. The filters are usually mounted on the circumference of a rotating wheel, thus permitting the acquisition of several different wavelengths. Although filters are an excellent means of wavelength selection, the filter wheel involves mechanical motion, which is prone to displacement errors or low reproducibility. Theoretically, an infinite number of filters can be placed on the filter wheel; however, in practice only a limited number can be used, ordinarily six to eight filters. Recently, CCD detectors have been merged with LCTF technology to produce wavelength-dependent images as shown in Figure 8. Each pixel in the spectral image would have a corresponding NIR spectral response. Likewise, AOTFs can be used in combination with CCD technology to produce wavelength-dependent images. However, AOTF spectral images tend to suffer from lateral chromatic aberrations resulting from the input design of the crystal. Both LCTFs and AOTFs have the advantage of no mechanical motion, an unlimited

3.3 Spectroscopic Imaging

In general, NIR spectroscopy using either broadband or discrete instruments is carried out at a single point on the in vivo tissue sample. The information acquired is localized to a distinct spot (1-cm diameter) on the tissue. Related to LCTFs, acousto-optical tunable filters (AOTF) are another means of a nonmechanical method of discrete wavelength selection over a broad wavelength range in the NIR region. AOTFs consist of a carefully cut tellurium dioxide crystal in which acoustic waves at radio frequencies are used to isolate a single wavelength of light from a broadband source. The acoustic wave propagating within the crystal alters the refractive index of the crystal. The crystal behaves like an enhanced diffraction grating in which multiple diffraction occurs over the volume of the crystal to produce a single wavelength output. The wavelength output is dictated by the acousto-optical properties of the crystal and the input radio frequency. Discrete wavelength selection is achieved by varying the frequency of the radio wave that is coupled into the crystal. The unique feature of the AOTF is its ability to adjust its transmitted light throughput by varying the radio frequency power to the crystal.
Figure 8 Schematic of a LCTF silicon CCD spectroscopic imaging system. The bright field image of a test card with a deposit of oil, blood and ink is presented along with the spectra associated with a pixel from each of the areas where a sample was deposited onto the card.

4 PRACTICAL CONSIDERATIONS

NIR attenuation spectra of living tissue can potentially provide information related to the physiological processes being probed as well as the anatomical structure of the tissue being investigated. However, in vivo spectra are strongly influenced by physical factors related to the measurement configuration, as well as the instrument-to-tissue interface. Often these latter factors are confounding and of little interest to the experiment, yet these factors can be significant contributors to the variation in the spectrum or between spectra. Sources of confounding variation and their effects on in vivo spectra must clearly be understood and accounted for in the analysis of in vivo tissue spectra.

4.1 Pulsatile Modulation

One complicating factor is the modulation of the optical attenuation of tissue by pulsatile blood flow. While this well-known phenomenon is exploited in pulse oximetry and photoplethysmography, pulsatile modulation represents a source of ~1 Hz noise when only the underlying tissue absorptions are of interest. Pulsatile modulation results from the cardiac cycle of the circulatory system, which is responsible for the transport of oxygenated blood to tissue. During the systole phase of the cardiac cycle the left ventricle contracts and causes blood to be ejected from the heart. At diastole the left ventricle refills with blood. In the peripheral vasculature, the systole-diastole phases of the cardiac cycle result in a modulated dilation and contraction of arteries and arterioles. This small difference in blood volume between the systolic and diastolic phases of the cardiac cycle produces the observed modulation in the attenuation of light by the tissue. This pulse due to blood volume change is heavily damped in the highly compliant venous system. The resulting pulsatile blood volume gives rise to a corresponding modulation in the optical attenuation which is largely localized in the arterial compartment of the circulatory system.

The pulsatile modulation depth of the optical attenuation of tissue depends on the vascular system being probed. In a highly vascularized tissue bed, the modulation depth can be as high as 15% of the signal. Figure 9 displays the mean ± SD of a time series of optical attenuation spectra collected over several hundred cardiac cycles at the index finger of the nonpreferred hand. Figure 10 displays the time course of the optical density of a finger tip at 800 nm over several cycles. The modulated optical signal has the same temporal contour as that measured by an arterial blood pressure catheter inserted percutaneously into a peripheral artery. The peak systolic and diastolic pressure points as well as the sharp incisura that coincides with the closure of the aortic valve and the cessation of ventricular ejection
Figure 9 Mean and standard deviation of time series of 2048 attenuation spectra from the index finger of the nonpreferred hand. Instrument noise is the cause of increasing standard deviation beyond 1000 nm. Arterial modulation is the cause of increasing standard deviation of the oxyhemoglobin vibronic bands at 540 and 576 nm as well as in the 850 nm region due to the broad charge transfer band of oxyhemoglobin.

Figure 10 Time course of the optical density at 805 nm from the index finger of a subject. Both diastole and systole phase of each cardiac cycle as well as the sharp incisura are clearly visible.

are clearly visible in the noninvasive optical reflectance signal.

The variability of the heart rate leads to a nonstationary time series as a result of fluctuations in both amplitude and in the temporal domain of the arterial blood pressure waveform. The power spectral density calculated from the spectroscopic time series is shown in Figure 11. Power spectral analysis of the temporal optical waveform clearly displays the ~1 Hz pulsatile modulation component. Variability in the heart rate is responsible for the distribution of frequencies at approximately 1 Hz in the estimate of the power spectral density plot. Data analysis of arterial blood pressure waveforms based on autoregressive and cross-spectral analysis as well as bivariate spectral (phase and coherence spectra) analysis are useful as an aid in detection of relevant cardiovascular pathologies such as hypertension and diabetes.\cite{48–50}

The light scattering properties of tissue are slightly altered by pulsatile modulation of tissue blood volume. However, the primary effect is on the absorption characteristics of the medium and oxygenated Hb absorptions are preferentially modulated by the 1 Hz pulsatile component. The preferential pulsatile modulation of oxyhemoglobin absorption features is related to the much higher Hb oxygen saturation in the arterial compartment of the tissue compared to the venous system and capillary beds. Mixed venous blood Hb oxygenation ranges between 72 and 78% and roughly reflects a global tissue oxygen measure. Arterial Hb oxygen saturation typically ranges between 95 and 98%.\cite{51} Pulse oximetry exploits this arterial compartment localization of the pulsatile modulation of the optical signal. Pulse oximetry monitors tissue reflectance or transmission at two wavelengths at which oxygenated and deoxygenated Hb have significantly different extinction coefficients. The fraction of oxygenated Hb is based on the magnitude of the differential absorption or reflectance at those two wavelengths. The static (DC) component of the signal is assumed to represent the fraction of oxygenated Hb within the volume of tissue which is being probed optically, while the time varying (AC) component of the reflectance response is largely attributed to the arterial compartment of that tissue volume. Arterial Hb oxygen saturation is empirically correlated with the AC component of the differential reflectance response. Thus, pulse oximetry provides a noninvasive measure of arterial Hb oxygen saturation.

Photoplethysmography determines peripheral arterial pressure waveforms by measuring the temporal shape of the optical reflectance over the cardiac cycle. Clinically, the magnitude of the pulsatile modulation of the optical signal correlates with the sufficiency of the arterial supply.
of blood to the peripheral tissue. The entire arterial pressure waveform can be used to assess peripheral resistance, arterial compliance and wave propagation and reflection. Thus photoplethysmography provides a useful noninvasive clinical diagnostic tool in evaluating the blood supply to the extremities as well as accessing the severity of peripheral vascular disorders.\(^{52-54}\)

Pulsatile modulation represents a source of 1 Hz variation in the in vivo NIR spectrum of human tissue. The spectral dependence of the pulsatile modulation of the optical attenuation of light between 500 and 1080 nm by tissue indicates that the modulated component of the signal provides information that is specific to the arterial compartment of the tissue that is being optically probed. While this has been exploited by pulse oximetry, spectroscopic analysis of the pulsatile modulated component of the tissue reflectance or transmission remains largely unexplored.\(^{55}\) This latter aspect may provide a more reliable means of analyzing blood specific analytes non-invasively using NIR spectroscopy.

Power spectral analysis of the time series of optical attenuation spectra (Figure 11) reveals a number of low frequency noise contributions to the signal in addition to the \(\sim 1\) Hz pulsatile component. One of the contributors to low frequency variation in the optical attenuation of tissue arises from respiration. Like the pulsatile component, modulation of the optical reflectance or transmission of tissue by respiration is site dependent. In addition, the experimental configuration can also have a profound effect on the magnitude of the respiration-induced variation of the optical signal. For instance, the contact pressure of the probe against the skin can be modulated by respiratory motion.\(^{56,57}\)

### 4.2 Probe–Tissue Contact Pressure

A number of confounding variables arise in measurement configurations that require a probe to come in contact with tissue. Contact pressure between the optical probe and tissue represents a serious source of error in the observed attenuation spectrum. The pressure exerted on the skin by the probe has a direct physical effect on the optical properties of the tissue. In some cases, it may also produce a blanching response in the underlying tissue.

The propagation of light through tissue is heavily influenced by scattering as a result of tissue inhomogeneity. Scattering is determined by the particle size, shape and distribution. As well as increasing the density of scattering centers in tissue, probe pressure against tissue squeezes out interstitial fluid and blood from the tissue. These factors modify the scattering properties of the underlying tissue and therefore influence the propagation of light in the tissue.

Capillary pressure in humans is in the range of 16 to 32 mmHg in the arteriolar limb and the forearm.\(^{58}\) Physical pressures exerted on the capillaries that exceed capillary pressures impede the flow of blood through the capillaries. When this occurs, the pressure forces blood out of the underlying cutaneous vessels, thus changing the blood volume present in the underlying tissue. Visually, a reduced blood volume in the tissue causes the appearance of a white spot (or blanch) in lightly pigmented skin. In more heavily pigmented skin, the visible absorption of melanin prevents the identification of a blanched region. A change in the blood volume of tissue changes both the intensity of the Hb absorptions and alters the scattering properties of the underlying tissue. This results in a major perturbation of the NIR attenuation spectrum of the tissue. While blood flow to a region is impaired, cells are deprived of oxygen and nutrients and waste products accumulate. The condition of restricted blood flow is called ischemia. If prolonged, ischemia may result in necrosis of the affected tissue.

When the source of pressure is removed, blood flow resumes and circulation of blood is restored to the blanched area. There is an inverse relationship between the amount of pressure exerted on tissue and the length of time before this pressure damages the tissue.\(^{59}\) If the time–pressure limits are exceeded, nonblanchable erythema may result. Nonblanchable erythema is a state in which pressure applied to skin does not cause a visible blanching response. This occurs as a result of tissue ischemia, caused by direct physical pressures exceeding capillary closure pressure for extended periods of time. Shear forces and friction also contribute to the development of nonblanchable erythema. Nonblanchable erythema is the first stage in the development of a pressure related wound or pressure sore.\(^{60}\) As the blanching response cannot be observed in darkly pigmented skin, other less reliable indicators (such as edema or warmth) must be used to determine the presence of first stage pressure sores in individuals with dark skin.

In general, NIR spectroscopy does not involve probe-to-skin contact for lengths of time or at such pressures that nonblanchable erythema, or more importantly severe tissue damage would result. However, varying the contact pressure between the probe and skin will alter the degree of blanch response in tissue. It is important to note that both tissue scattering and tissue blood volume are altered in the region being probed spectroscopically as a result of the varying pressure applied to the surface of the tissue.

Analysis of the mean NIR reflectance response (1000–2400 nm) from skin and the probe-to-skin contact pressure indicates that probe-to-skin contact pressure is highly positively correlated \((0.85)\) with the mean reflectance response from skin. Fluctuations in the probe-to-skin contact pressure thus result in a varying NIR
reflectance and can represent a major source of variation in the reflectance response from tissue. The spectral dependence of the correlation between contact pressure and single-beam reflectance shows a distinct correlation pattern (Figure 12). If the spectral regions where water strongly absorbs are ignored, there is an overall negative slope in the positive correlation as a function of increasing wavelength. This behavior may be interpreted as the decreasing influence of tissue scatter on the overall light attenuation by tissue at longer wavelengths. Therefore, pressure induced changes in the tissue scatter function have a diminished effect on the attenuation of the longer wavelengths of NIR light by tissue.

The subtle slope change in the pressure–reflectance correlation spectrum is overshadowed by the large drop in reflectance–pressure correlation in the regions that are characterized by strong spectral absorptions. The most prominent feature is the large change in correlation over the OH stretch–bend combination region (1800–2000 nm). The OH stretch overtone/combination region (~1400 nm) displays a much smaller drop in pressure–reflectance correlation compared to the stretch–bend combination region. At wavelengths beyond 2200 nm the correlation drops dramatically as light attenuation by the tissue increases.

The anomalous reflectance–pressure correlations that occur in the region of the strong NIR absorptions of water arise from pressure induced blood volume changes. Fluid becomes displaced from the optical path when probe contact pressure is increased. Fluid displacement results in a decrease in the water absorption related attenuation of the NIR light. As the absorption coefficient of the water increases from the OH stretch overtone/combination region (~1400 nm) to the OH stretch–bend combination region (1800–2000 nm), the magnitude of this effect is expected to be greater at the longer wavelength water absorption band. In spectral regions where light attenuation is dominated by water absorption, pressure-induced fluid displacement and the resulting decrease in absorption offset the increase in NIR light attenuation due to higher probe pressure against the skin.

Unlike the variation induced by pulsatile blood flow, the pressure exerted on the tissue by an optical probe is a variable that can be controlled by the experimenter. Another condition that the investigator must take note of is the effect of tissue temperature on spectroscopic measurements. This is another aspect where variability can be controlled.

4.3 Tissue Temperature

The optical properties of tissue are temperature dependent. Qualitatively, the scattering of light by tissue can be thought of as arising from microscopic discontinuities in the refractive index within the tissue medium. For example, such discontinuities or boundaries exist at the interface between the cell membrane and the extracellular matrix. Since the refractive index of a medium is strongly temperature dependent, the scattering of light by tissue is expected to be sensitive to changes in tissue temperature. In addition to this direct influence on the optical scattering properties of tissue, temperature variations indirectly change the optical properties of tissues due to the potent vascular response to a local change in temperature. Since both the direct physical and physiological consequences of varying tissue temperature have significant effects on tissue optics, these effects must be taken into account in the analysis of in vivo NIR attenuation spectra of tissue.

![Figure 12](image1.png)  
**Figure 12** Pearson correlation coefficient between probe-to-skin contact pressure and skin reflectance measured between 1000 and 2400 nm on the abdomen of a group of six study volunteers. Each subject was measured for a 2 h period and the cumulative with-in and between subject pressure–reflectance correlation is reported.

![Figure 13](image2.png)  
**Figure 13** Representative traces of the reflectance response between 1000 and 2400 nm of the abdomen of a subject with a skin temperature of 20 and 40 °C.
As with the other confounding factors that have been discussed, the physiological response to a change in tissue temperature varies considerably depending on the type of tissue and the site. For instance, thermoregulatory systems can significantly alter superficial skin blood flow and cutaneous blood volume when skin temperature is changed. In Figure 13 the reflectance response over the range 1000–2400 nm from the upper abdomen of a subject is compared at 20° C and 40° C. In Figure 14 the difference in the reflectance response of the upper abdominal site at 40° C and 20° C are compared over a study population consisting of 17 subjects. Figure 14 clearly indicates that both the magnitude and the wavelength dependence of the reflectance response to varying skin temperature are highly reproducible over the study population. The upper abdomen consistently had a higher reflectance at 40° C. Figure 15 plots the correlation coefficient between skin temperature and reflectance responses from the abdomen over the course of a 2 h temperature ramping protocol carried out in a study group of 17 subjects. The reflectance response shows a significant high positive correlation (+0.77) with the temperature of the abdomen in the temperature ramping protocol. The high positive correlation between the reflectance response and skin temperature over most of the 1000–2300 nm wavelength region (Figure 15) is considered to be due to the temperature dependence of the scattering properties of the tissue. It is absent in the corresponding correlation spectra obtained from temperature ramp experiments using nonscattering aqueous media where the thermal volume displacement has been accounted for. Ignoring the spectral regions where water absorbs strongly, an overall negative slope in the positive correlation between reflectance and skin temperature is observed as a function of increasing wavelength. As noted in the previous section, the gradual drop in the correlation between skin temperature and reflectance at longer wavelengths arises from the decreased importance of scatter to the overall attenuation of light by the tissue. The decreased contribution from scattering at longer wavelengths results in a smaller general temperature effect on the overall attenuation of light by tissue in the spectral regions devoid of water absorptions.

Skin temperature–reflectance and pressure–reflectance correlation spectra differ in detail in the regions of the spectrum dominated by strong water absorptions. The observed decreased attenuation of light by water absorption as a function of probe contact pressure arises from the displacement of interstitial fluids and blood from the underlying tissues due to the applied pressure. The magnitude of this pressure effect was observed to be proportional to the extinction coefficient of water. However, the correlation between the reflectance response from skin and skin temperature over a water absorption band is not strictly a function of the extinction coefficient of water at each wavelength. Water absorption bands are known to be extremely temperature sensitive. In particular there is a temperature dependent shift in the maxima of the water absorption bands. These band shifts give rise to the sharp derivative-type features and regions of negative correlation in the skin temperature–skin reflectance correlation spectra.
Variation of tissue temperature has a profound effect on the scattering properties of the medium. Superimposed on the effect of temperature on tissue scattering, temperature dependent spectral shifts in water absorption bands give rise to more subtle variations in tissue spectra. These combined effects are difficult to model and can represent a serious confounding factor in the realm of in vivo spectroscopy. Often they are simply ignored or overlooked. Of particular concern are situations where the variation in tissue temperature is correlated with the intervention or manipulation of interest that is being monitored spectroscopically.

5 SELECTED EXAMPLES

To date, in vivo NIR spectroscopy is primarily applied to the assessment of tissue perfusion and oxygenation of tissue. Tissue blood perfusion is a key element in the thermoregulation of tissue. Disruptions of blood flow, ischemia, or poor blood perfusion will often result in a drop in tissue temperature. Thus when NIR spectroscopy is used to determine the extent of ischemia or the degree of reperfusion, perturbations in the attenuation spectra related to tissue temperature must be considered. Preferably, they should be compensated for at the outset in the experimental design.

Detection and monitoring of poorly perfused (ischemic) and poorly oxygenated (hypoxic) tissue remains an important issue in many fields of medicine and biology. NIR spectroscopy offers a noninvasive means of assessing the balance between tissue oxygen delivery and oxygen utilization. Monitoring the relative concentrations of oxygenated and deoxygenated Hb provides a measure of Hb oxygen saturation of tissues. NIR spectroscopy can determine information about the status of tissues at one point in time, or by monitoring a time series of spectra, it is possible to monitor changes as a function of time. Combining these capabilities and using an array detector, the spatial–temporal distribution of oxygenated and deoxygenated Hb in tissue can be imaged. Oxygen consumption through mitochondrial respiration can be inferred from changes in the visible–NIR spectra that arise due to a shift in the redox state of cytochrome oxidase during hypoxia. Reduced and oxidized cytochrome oxidase have distinct visible–NIR absorption spectra bands and thus, significant alterations in the ratio of reduced to oxidized enzyme in tissue can be determined spectroscopically. Time series of spectra are very useful for monitoring changes that occur during ischemia and reperfusion.

5.1 Forearm Ischemia–Reperfusion

The human forearm and leg have been convenient investigation sites for many of the noninvasive NIR studies that have examined the local response of tissue to manipulations of blood flow. A disruption of blood flow (ischemia) to the arm can be produced by arresting circulation to the forearm with a pressure cuff, effectively impeding both arterial inflow and venous outflow. During ischemia, blood present in the forearm becomes increasingly deoxygenated. As deoxygenation progresses, the oxyhemoglobin doublet attenuates and is replaced by a single broad peak, centered on 564 nm (see Figure 2). This peak is characteristic of deoxyhemoglobin. NIR spectroscopy can detect similar oxygen related changes to the spectrum that occur during ischemia. The significant increase in optical density during ischemia in the region of the charge-transfer band of Hb at 760 nm is consistent with the increased fraction of Hb in ischemic tissue and is perhaps the clearest indicator in the NIR of the change in Hb oxygenation during ischemia. The relative concentrations of Hb and HbO2 can be monitored by fitting the NIR attenuation spectra to the extinction coefficients of the chromophores.

Figures 16 and 17 compare the laser Doppler measure of blood flow throughout the ischemia–reperfusion protocol with the change in the calculated concentrations of [Hb] and [HbO2] obtained from the ischemia–reperfusion time series of NIR spectra. The sum of [Hb] and [HbO2] provides a measure of the total amount of Hb (tHb) present at any point in time. The steep drop in blood flow illustrated in Figure 16 corresponds to the inflation of the pressure cuff. As expected, [Hb] begins increasing as soon as the blood flow is cut off. The tissue consumes the limited amount of oxyhemoglobin, causing [HbO2] to decrease during circulatory arrest to the forearm. It is apparent in

Figure 16 Laser Doppler flux measure of the change in forearm blood flow during a forearm ischemia–reperfusion protocol.
As the excess interstitial adenosine is washed of blood to flow through that region, resulting in reactive state of the vascular system permits an increased volume very dilated. When ischemia is relieved, the locally relaxed adenosine, ischemia causes the blood vessels to become of interstitial adenosine. As a result of the accumulated triphosphate (synthesized from adenosine) it to accumulate. Additionally, the aerobic production of adenosine triphosphate is strongly correlated with the laser Doppler measure of washout of interstitial adenosine is prevented, causing hypoxia is termed hypoxemic hyperemia. As tissue oxygen concentration decreases during ischemia, the vascular system attempts to compensate by adjusting vascular resistance. Blood vessel walls contain a layer of smooth muscle that is very sensitive to the interstitial concentration of adenosine, a potent vasodilator. Under normal circumstances, the interstitial concentration of adenosine remains stable. However, during ischemia the normal washout of interstitial adenosine is prevented, causing it to accumulate. Additionally, the aerobic production of adenosine triphosphate (synthesized from adenosine) is arrested. This also contributes to the accumulation of interstitial adenosine. As a result of the accumulated adenosine, ischemia causes the blood vessels to become very dilated. When ischemia is relieved, the locally relaxed state of the vascular system permits an increased volume of blood to flow through that region, resulting in reactive hyperemia. As the excess interstitial adenosine is washed out, the vascular smooth muscle becomes less dilated and normal circulation resumes.

During hyperemia, the increase in blood volume is naturally accompanied by an increase in tHb. As the influx of blood is arterial, it is highly oxygented. This causes an increase in [HbO2]. Meanwhile, [Hb] decreases dramatically through venous washout. Note that in Figures 16 and 17 the flux, [Hb] and [HbO2] return to their preischemic levels following hyperemia.

During ischemia the NIR tissue attenuation spectrum displays both an increased baseline offset and a quasi-linear wavelength dependent slope change. These features are characteristics of change in the scattering properties of the tissue. The increased blood volume associated with the hyperemic phase of the protocol has the opposite effect on the baseline offset and causes a reciprocal change in the slope of the spectrum. As the blood volume approaches the level that existed prior to ischemia, the spectrum offset and slope return to the level observed in the spectra acquired during the preischemia phase of the protocol.

NIR spectroscopic studies examining the response of the forearm to brief periods of ischemia followed by reperfusion clearly indicate that the measured changes in the attenuation spectrum of the tissue correlate with periods of changing forearm blood flow and blood volume, as well as oxygenation. The calculated changes in the concentrations of Hb, HbO2 and therefore tHb and Hb oxygen saturation are weakly dependent on the range of wavelengths used to fit the spectra. The calculated concentration values are also dependent on the distance separating the light source and the light collector. Despite these shortcomings, crudely fitting the NIR attenuation spectra to the extinction coefficients of Hb and HbO2 provides a trend monitor for the change in the relative concentrations of these species. Therefore this method provides a measure both of the oxygen delivery to the forearm and of the forearm blood volume. Early forearm studies demonstrated the potential of NIR spectroscopy to monitor the degree of tissue ischemia and the extent of reperfusion. Since then clinical interest has largely focused on developing NIR spectroscopy as a means of detecting cerebral ischemic events in high risk, low birth weight neonates as well as for monitoring skeletal muscle during exercise or the heart during surgery.

5.2 Myocardial Ischemia–Reperfusion

The ability of NIR spectroscopy to determine the oxygenation status of myoglobin makes it extremely useful for monitoring the consumption of oxygen by working muscle. Consequently, NIR spectroscopy is being increasingly applied in the area of sports medicine. The heart muscle has also been studied by NIR spectroscopy. Myocardial ischemia is extremely detrimental to cardiac function. Even a few minutes of ischemia may cause damage to the heart. Damage may contribute to exacerbation of infarction, impairment of contractile or conductive abilities or it may cause vascular
dysfunction.\(^\text{83}\) Reperfusion of the heart may also cause damage, through mechanisms similar to those in muscle and brain tissue.\(^\text{84}\) Myocardial ischemia occurs as a result of occlusion or a spasm of a coronary artery leading to a reduction or complete cessation of blood flow to the area perfused by the affected vessel. In addition, ischemia is encountered during surgical procedures requiring aortic cross clamping. NIR spectroscopy has been used to measure cardiac oxygenation\(^\text{79–81}\) and tissue pH.\(^\text{82}\)

Langendorff perfused rat hearts provide a useful model for examining myocardial ischemia–reperfusion. The absence of blood in this system permits the observation of myoglobin, without interference from Hb. When both Hb and myoglobin are present in a tissue sample, it is quite difficult to tell them apart, spectroscopically. In the absence of Hb, NIR spectroscopy can distinguish the fraction of oxygenated myoglobin based on the distinct spectral characteristics of oxy- and deoxy-myoglobin.

Figure 18 summarizes the results obtained from a series of spectroscopic and functional measurements made on eight Langendorff perfused rat hearts over the course of an ischemia–reperfusion protocol. Figure 18 compares the raw spectral means obtained from the full study group from the preischemia, ischemia and reperfusion segments of the protocol. Statistical analysis on the raw data indicates that the NIR attenuation (\(\lambda > 650\) nm) changes significantly (\(P < 0.05\)) over the ischemia–reperfusion protocol. This effect arises largely from the change in the scattering properties of the tissue during ischemia and reperfusion relative to scattering properties of the myocardium prior to ischemia. In the short wavelength

\(\lambda = 650–1000\) nm, the attenuation of light by tissue is dominated by scattering. A small change in tissue scatter function can markedly affect the attenuation of NIR radiation by tissue. This is evident from the mean spectra and mean difference spectra presented in Figures 18 and 19 respectively. There is a significant offset and slope change in the NIR between preischemia, ischemia and reperfusion. Post-hoc means comparisons indicate that tissue scattering changes most dramatically at reperfusion resulting in decreased NIR reflectance from the heart.

The tissue scatter coefficient is highly temperature dependent. Strict temperature control throughout all segments of the experiment is crucial in order not to introduce temperature-related artifacts in the optical attenuation of the tissue. Statistical analysis indicates that the changes observed in the spectral time series are not significantly correlated with the measured temperature variations over the experiment and that heart temperature does not change significantly over the various segments of the ischemia–reperfusion protocol. The observed change in spectral offset and slope can be rationalized in terms of a varying mean photon pathlength over the ischemia–reperfusion protocol. These changes in the scattering properties of the tissue over the spectral time series would appear to arise as a direct result of ischemia–reperfusion on the heart as opposed to a secondary tissue temperature effect. Successfully accounting for the scatter-induced variation in the spectra would enable absolute myoglobin oxygenation changes to be determined by fitting the Mb and MbO\(_2\) extinction coefficients to the scatter-corrected NIR spectra.

In vivo NIR spectra over the 700- to 900-nm region are usually fit to the extinction coefficients of three chromophores, [Hb, Mb], [HbO\(_2\), MbO\(_2\)] and [Cytaa\(_3\)]\(_{\text{oxidized}}\) minus [Cytaa\(_3\)]\(_{\text{reduced}}\). The ischemia–reperfusion-related changes in the tissue-scattering function are often ignored,
or it is assumed that the scattering losses do not change over the protocol. The water contribution is also ignored despite the fact that water has two absorption bands in the spectral region used by most of the fitting routines. This omission is generally rationalized by the assumption that tissue water content is constant and does not change over the duration of the protocol. In Langendorff heart preparations, failing to account for the correlated changes in tissue scattering and water content confounds the calculated changes in the chromophore concentrations over the course of the ischemia–reperfusion protocol.

The correlated scatter-related changes in the attenuation spectrum present a particular problem when trying to determine changes in the redox state of CuA, the copper metal center of cytochrome c oxidase. The differential NIR absorption of the oxidized and reduced CuA center of the enzyme, $\text{[Cytaa}_3\text{]}$, at around 830 nm are difficult to differentiate in the presence of tissue oxygenation changes and changes in the scattering characteristics of the tissue. Based on three chromophore fits without accounting for water and scatter changes in the spectra, it is by no means clear that the time series of redox state changes of $\text{[Cytaa}_3\text{]}$ represents changes in the enzyme absorption characteristics or whether the changes are due to the scatter-related changes in the spectra or residuals from the fit to $[\text{Hb}, \text{Mb}]$ and $[\text{HbO}_2, \text{MbO}_2]$. In general, the highly correlated response across the NIR effectively masks more subtle spectral features associated with enzyme CuA oxidation–reduction and makes unequivocal assignment of these redox-related changes in the CuA absorption feature of the enzyme difficult.

When superficial tissues are investigated, the visible heme $a + a_3$ transition can be used to monitor the metabolic activity of the mitochondria.$^{85,86}$ Upon reduction of the heme $a + a_3$ center of cytochrome $c$ oxidase the heme $\alpha$-band shifts from 590 to 605 nm and increases in intensity. The increase in intensity of the visible heme $\alpha$-band upon reduction is the opposite behavior compared to NIR CuA absorption feature of the enzyme. Therefore the use of both the visible heme $a + a_3$ transition and the NIR CuA absorption feature would appear to be a prudent strategy to track mitochondrial oxygen utilization.

The heme $\alpha$-band of cytochrome $c$ oxidase lies on the shoulder of the intense visible $Q_o$ Hb/myoglobin vibronic transition. The broad $Q_o$ band of deoxyhemoglobin/myoglobin has a higher extinction coefficient in the long wavelength visible compared to the corresponding transition when the heme is oxygenated. Thus, simply monitoring the attenuation in the region between 590 and 620 nm will once again produce results that are heavily confounded by Hb/myoglobin oxygenation changes. Difference spectroscopy in which reference $Q_o$ and $Q_i$ Hb/myoglobin visible vibronic transitions are subtracted from the spectrum can be used to visualize changes in the heme $\alpha$-band of cytochrome $c$ oxidase. Line narrowing methods such as Fourier self deconvolution$^{87}$ and linear prediction extensions of the method$^{88}$ are often extremely useful in resolving overlapping spectral features and may offer a means of extracting the heme $a + a_3$ center oxidation changes more cleanly. Figure 20 compares visible attenuation spectra processed using the LOMEP$^{89}$ (linear shape optimized maximum entropy linear prediction) line narrowing procedure. The reduced heme $\alpha$-band of cytochrome $c$ oxidase becomes apparent in the processed spectra during myocardial ischemia. The integrated intensity of the isolated heme $\alpha$-band is plotted over an ischemia–reperfusion protocol in Figure 21. In this Langendorff preparation reduction of the heme $a + a_3$ center which results in an increase in the integrated area of the isolated heme $\alpha$-band closely tracks oxygen delivery to the heart. Higher attenuation at 610 nm upon ischemia relative to preischemia and reperfusion is consistent with the accumulation of reducing equivalents of the heme $a + a_3$ center in the absence of molecular oxygen.

The positive optical density at 610 nm in the reperfusion minus preischemia difference spectra indicates that the redox balance of heme $a + a_3$ center of cytochrome $c$ oxidase is not fully restored after reperfusion. A higher fraction of the enzyme is reduced relative to the preischemic state. The increased fraction of reduced enzyme following reperfusion may be a good indicator of the degree of functional damage to the heart caused by the ischemia–reperfusion sequence.

Chromophore concentration changes determined from the series of NIR spectra are consistent with the changes

![Figure 20](https://example.com/figure20.png)

**Figure 20** LOMEP resolution enhanced visible spectrum of the myocardium preischemia (——) and during ischemia (····). The heme $\alpha$-band (heme $a + a_3$ transition) of cytochrome $c$ oxidase increases in intensity upon reperfusion indicating an accumulation of reducing equivalents of the heme center during ischemia.
Figure 21 Time course of the integrated area of the heme \( \alpha \)-band of cytochrome \( c \) oxidase. Reduction of the heme center of the enzyme results in an increase in heme \( \alpha \)-band intensity. The three preconditioning ischemic events and the longer 20 min ischemic period are clearly present in the time trace. Following the 20 min ischemia, the redox state of the heme center of the enzyme does not fully return to its preischemia condition indicating cellular damage to the heart.

Figure 22 Changes in myoglobin concentration based on simultaneously fitting the extinction coefficients of \([\text{Cytaa}_3]_{\text{oxidized}} - [\text{Cytaa}_3]_{\text{reduced}}\), \([\text{Mb}]\), \([\text{MbO}_2]\) and \([\text{H}_2\text{O}]\) as well as a scatter offset correction to the time series of NIR spectra covering the region between 740 and 880 nm.

Figure 23 Change in the water content of the myocardium during the ischemia–reperfusion protocol. These results indicate an increased water content of the heart tissue over the time course of the protocol as well as a reversible loss of water during the ischemic phases of the protocol.
function. While this assumption does not hold over the full range of the NIR, the approximation seems reasonable when only a short wavelength segment of the NIR is used to fit the extinction coefficients of the major absorbing chromophores. A related scheme that has attracted much attention in the literature uses the weak water absorption bands at 730 and 840 nm to perform a scatter correction. A second derivative of the spectrum is taken in order to eliminate the offset and the linear wavelength-dependent contribution of the scattering loss from the spectrum. The amplitude of the second derivative water absorption features are fit to a second derivative reference water spectrum to provide a scale factor that is then divided by the assumed water concentration to provide an effective photon pathlength (usually referred to as the differential pathlength factor). This method implies that tissue water concentration remains constant over the time series of spectral measurements and that changes in the second derivative amplitude of the 730 and 840 nm water features arise solely from the scatter dependence of the mean photon pathlength.

While the constant tissue water assumption may hold in a number of circumstances, as this example points out it is not always possible to make this assumption. In this example of myocardial ischemia–reperfusion, there is a significant increase in tissue edema over the course of the protocol. This leads to a severe breakdown of the constant tissue water assumption. At best in this example, the second derivative water correction provides a measure of the [Mb] to [H2O] ratio in the tissue, allowing this trend to be monitored. For the reasons mentioned above, without an explicit determination of the optical scatter function of the sample tissue, the conversion of an attenuation spectrum into absolute chromophore concentrations is problematic. While baseline offset, multiplicative scatter correction and second derivative fit to water attempt to correct attenuation spectra for variations in the tissue scatter function each method has its limitations and shortcomings. Time and phase-resolved methods offer a means to obtain scatter correction factors at discrete wavelengths that can then be used to correct conventional attenuation spectra. Increasingly these approaches, particularly phase-resolved measurements, are being relied upon to correct attenuation measurements for the scattering contribution to the measured loss. Another approach to determining changes in tissue scatter function is to simultaneously monitor several source–collector separations. This method effectively measures the attenuation losses at several different mean photon pathlengths. This approach, sometimes referred to as spatially resolved spectroscopy, can be used to determine the scattering component of the attenuation loss, assuming that the different volumes of tissue that are sampled by each source–collector pair have the same effective scattering coefficient.

The conversion of NIR attenuation spectra of tissue into absolute measures of [Hb, Mb], [HbO2, MbO2] and [Cytaa3]oxidized minus [Cytaa3]reduced remains a key issue in the development of a reliable tool for the clinical assessment of oxygen delivery and cellular respiration. While the visible heme a + a3 transition can be monitored with reasonable ease when the optical pathlength is relatively short, the strong attenuation of visible light by tissue limits the penetration depth to superficial tissues. The weak differential NIR absorption of the oxidized and reduced CuA center of cytochrome c oxidase is extremely difficult to extract in the presence of highly correlated spectral changes related to changes in Hb/myoglobin oxygenation and tissue scattering. This is particularly the case with deep tissue oxygenation applications of NIR spectroscopy such as cerebral oximetry for which few if any reference methods exist to aid in the calibration or refinement of algorithms aimed at providing absolute chromophore concentrations from NIR attenuation data.

5.3 Cerebral Oxygenation and Blood Flow

NIR spectroscopy has been extensively used to monitor the oxygenation of the brain. The functional monitoring of cerebral activity following activation or stimulation using both NIR spectroscopy and magnetic resonance functional imaging techniques has recently received much attention. Clinical monitoring of cerebral oxygenation in high-risk neonates and during cardiopulmonary bypass also remain important clinical applications of NIR spectroscopy.

Neonatal applications are mainly concerned with the incomplete development of autoregulatory control mechanisms governing cerebral blood flow. This commonly leads to incidents of cerebral ischemia and intraventricular hemorrhage in the low birth weight neonate population. These complications have devastating acute mortality and morbidity consequences on this population. Cerebral ischemia and intraventricular hemorrhage are also associated with a high risk of long-term neurological damage. There are a number of other conditions that place the oxygenation of the brain at risk in the newborn population, including birth asphyxia, traumatic head injury, near-drowning and cardiopulmonary bypass surgery. Currently there is no reliable or routine means of clinically monitoring cerebral oxygenation. NIR spectroscopy offers the potential of detecting cerebral circulation deficits by directly monitoring cerebral oxygenation, cerebral blood volume and blood flow. Considerable work has been carried out to develop a reliable clinical cerebral oximeter based on NIR spectroscopy.
NIR cerebral oximetry suffers from the confounding factors and complications that were described in the examples dealing with the investigation of superficial tissue oxygenation. However, deep tissue oximetry is complicated by additional factors. Oxygenation changes or changes in the optical properties of the surface and superficial tissues are generally not of interest in deep tissue oximetry applications. In cerebral oximetry applications, oxygenation changes of the scalp or changes in the optical properties of the skull must be discriminated against. The usual strategy that is employed is to ensure that the scalp and skull represent a minor component of the volume of tissue that is sampled by the collected photons. This can be achieved by an instrumental set-up in which the separation between the light source and the light detector/collector is adjusted to ensure that large tissue volumes are sampled. In human neonate cerebral oximetry, source–collector separations >1 cm are typical. Thus the tissue attenuation spectrum is heavily weighted to that of the cerebral tissue.

While it has been widely demonstrated that NIR spectroscopy can measure relative changes in cerebral oxygenation, absolute determination of [Hb] and [HbO2] remain elusive. This causes absolute measurement of total Hb concentration or blood volume measurement to be problematic as well. In addition, cerebral Hb oxygenation is affected by neurological activity. In an ischemic region with minimal cerebral blood flow but abolished neuronal activity, Hb oxygenation may be normal despite the fact that the tissue is rapidly evolving to infarction. In these instances, a corresponding measure of cerebral blood flow values based on a modification of Fick’s Principle in which the flow value is determined within the transit time of the tracer. When this assumption is fulfilled, venous outflow of the tracer can be ignored and the kinetic model is simplified. However the short tracer transit times in the brain, ~4 s, severely limits the quality of NIR measurement sequence that can be acquired. To date these measurements of cerebral blood flow have suffered from extremely high variability. This has led investigators to question the validity of cerebral blood flow values determined by this approach. More extensive kinetic modeling of the tracer impulse–response profiles may help provide greater consistency in the NIR-based measures of cerebral blood flow.

Considerable effort has gone into the development of NIR spectroscopic techniques to determine absolute cerebral oxygenation, blood volume, blood flow and the redox balance of the CuA center of cytochrome c oxidase. In spite of all this, enormous challenges remain. These NIR methods require further development and innovation to make them clinically practical and reliable and thereby fulfill the goal of having an inexpensive, portable bedside monitor able to detect cerebral circulatory deficits.

4.5 Near-infrared Assessment of Tissue Viability

There are clinical situations where the local oxygenation of tissue is of critical importance and it is in these situations that NIR spectroscopy may be the most useful. Determining the oxygenation of tissue that is near the surface of the skin is particularly accessible for NIR spectroscopic interrogation. Adequate oxygen delivery to wounds and reconstructed or transplanted tissue is requisite for proper healing. In the case of a burn injury, a key clinical question is whether the underlying tissue has the capacity to heal itself given proper wound care or whether the damage will extend over the full thickness of the skin. Full thickness injuries require tissue replacement usually in the form of skin grafting. Chronic poorly healing...
wounds or dehiscent amputation sites generally suffer from inadequate blood perfusion (hypoperfusion) and poor oxygenation (hypoxia). Treatments are generally aimed at improving oxygen delivery to the wound site. Flaps and grafts form the basic procedures used in surgical reconstruction of skin and muscle. Following surgical elevation, the flap or graft experiences adverse circulatory changes that limits the supply of blood to the tissue and results in hypoxic sections of the graft or flap. Early and reliable assessment of the degree of compromised tissue perfusion has important clinical implications for the ultimate survival of tissue. The utility of NIR spectroscopy and imaging is being explored to determine peripheral vascular perfusion, oxygenation of skin flaps and skin grafts as well as its suitability as a general tool for the assessment of oxygenation and hemodynamics of superficial tissues during surgery.

NIR spectroscopy is well suited to the assessment of oxygen delivery to compromised cutaneous tissue. The tissue under investigation in these applications is superficial, being at or near the surface of the skin. Small distances (<1 cm) between light source and collection optics (or detector) can be used to ensure that small tissue volumes are being predominantly sampled and thus near surface tissues are largely being probed in this configuration. This considerably simplifies the interpretation of the NIR spectral response compared to deep tissue investigations where the response from confounding superficial tissue is superimposed on the deep tissue spectral information. If only the upper surface of the tissue is being investigated, noncontact reflectance measurements can be made. This eliminates artifacts arising from the instrument–tissue interface. The shorter photon pathlengths that are typically sampled in the near surface applications enable a wider spectral range to be sampled. Visible (400–650 nm) and long wavelength NIR (1000–2500 nm) reflectance from tissues can be measured in the noncontact reflectance configuration or when source collector separations are on the order of 1 mm. Despite the fact that tissues are highly scattering in the NIR, image contrast is maintained for several scattering lengths. Thus NIR imaging can be used to resolve near surface features in tissues.

Clinicians empirically rely upon the visible appearance of tissue in the routine assessment of viability of tissue. Cyanosis, tissue swelling and desiccation provide important visual clues as to the status of skin flaps, chronic wounds or burn sites. Unfortunately, these differences only become clinically apparent several hours or days after the onset of the complication. The late manifestation of the clinical symptoms hampers early recognition of complications and often delays interventions aimed at alleviating the complication. Tissue swelling or the formation of edema affects the optical properties of the tissue in the NIR. Likewise tissue desiccation or dehydration along with cyanosis also profoundly affect the visible–NIR spectrum of tissue. Thus, well-perfused, healthy tissue and poorly perfused, compromised tissue will have different NIR spectral features.

The reversed McFarlane skin flap model provides an excellent model for demonstrating the capabilities of NIR spectroscopy and spectroscopic imaging of compromised cutaneous tissues. The model is illustrated in Figure 24. A pedicle skin flap is raised on the back of the rat. The base of the flap remains attached to an existing blood supply provided by the dorsal sacral vessels. The base of the flap is generally referred to as the vascular pedicle and provides the blood supply to the remainder of the skin flap. In this model, the flap is too long for the existing blood supply. The section of the flap proximal to the vascular pedicle remains well perfused and healthy while the section of the flap distal from the pedicle receives little if any blood supply. The central section of the flap is generally underperfused and ischemic. In the reverse McFarlane model, the distal section of the skin flap generally fails within 72 h of raising the flap while the proximal section remains healthy. The fate of the central section of the flap is less predictable and depends on the number and size of sacral vessels feeding the flap, the quality of the surgery and whether vascular complications arise as a result of the surgery or infection. NIR spectroscopy is best able to determine relative concentrations of oxy- and deoxyhemoglobin or changes in the concentrations of these species rather than providing an absolute concentration measurement. Similarly relative tissue water content or changes in tissue water content can be determined spectroscopically.

Figure 25 compares NIR attenuation spectra of the central site of a rat’s dorsum taken before and after elevation of the skin flap. Fitting a time series of attenuation spectra to the extinction coefficients of Hb, HbO2, H2O and Cytaa3 provides a measure of the relative concentration of these species and the temporal change of
concentration of these chromophores in the tissue. Based on the relative changes in the Hb, HbO₂ concentrations, the degree of tissue oxygenation can be determined. Figure 26 presents the temporal change in the percent Hb oxygen saturation over a 120-h period measured at 6-h intervals at the proximal, central and distal sites on the dorsum of a rat. Hb oxygenation over the dorsum remains relatively constant prior to surgery. However, following surgery at the 60-h monitoring point the oxygenation of tissue at the central and distal sites drops dramatically. Following the initial drop in oxygenation after surgery the oxygenation of the central site remains relatively stable over the remaining 60 h of monitoring. Oxygenation at the distal site continues to drop after surgery. Tissue at and around this distal measurement site dies over the intervening 60 h of monitoring. Over the course of the 60-h postoperative monitoring period, oxygenation at the proximal site remains relatively unchanged from that measured at that site prior to surgery. While the ratio of concentrations of HbO₂ and Hb can provide a measure of tissue oxygenation, the sum of the concentrations provides a relative measure of tissue blood content (or blood volume). Figure 27 presents a time series of tHb images derived from NIR spectroscopic imaging sequences of the rat dorsum prior to surgical elevation of the flap and at 5, 60, 120 and 720 min following surgery. tHb images provide insight into the blood volume distribution in the skin flap. Prior to surgery the rat dorsum has a relatively uniform tHb distribution. Immediately following surgical elevation of the flap, a gradient in the tHb concentration exists along the length of the flap. tHb proximal to the vascular pedicle at the base of the flap is not significantly different from the tHb level of the surrounding uninvolved tissue of the rat dorsum. However, the tHb levels along the flap drop with increasing distance from the vascular pedicle. This blood volume (tHb) distribution persists in the flap for the duration of the experiment. These results are consistent with the tissue oxygenation findings. The NIR spectroscopic imaging and point spectroscopy clearly indicate that the central region of the flap remains ischemic and hypoxic following surgery but the tissue can generally cope with this level of underperfusion. The distal site shows a more dramatic drop in oxygenation and blood volume over the first 2 h following surgery and this site generally fails within the intervening 60 h. Figure 27 also shows the fractional change in tissue water.

Figure 25 NIR attenuation spectra from a central site on the dorsum of a rat before (—) and after (· · ·) elevation of a skin flap.

Figure 26 Change in percent Hb oxygenation at the proximal (——), central (· · ·) and distal (· · ·) measurement sites on the rat dorsum measured over a 120 h monitoring period at 6-h intervals. Skin flap was elevated after 60 h of monitoring.

Figure 27 (a) Time series of total Hb images of a rat dorsum derived from spectroscopic imaging sequences taken immediately prior to elevation of the flap (0 min) and at 5, 60, 120 and 720 min following elevation of the skin flap. Image intensity is proportional to the total Hb content in the tissue. (b) The corresponding time series of hydration images of the same flap. Image intensity is proportional to the water content of the tissue.
content over the same flap in which the tHb was reported. Following surgery the proximal site experiences a small increase in tissue water content. After 72 h, tissue water content at the proximal site returns to its pre-surgical level. The central site shows no significant change in hydration over the course of the experiment. Conversely, the water content at the distal site drops dramatically upon surgery and continues to drop over the first 12 h. The drop in blood volume or tHb, Hb oxygenation and tissue hydration are clear indicators of hypoperfusion of the distal sections of the flap. These indicators appear early in the post-operative period, well before there are overt clinical symptoms of tissue compromise. Figure 28 compares a NIR Hb oxygen image of a flap 1 h after surgery with a corresponding visual image and a visual image taken 72 h later. The regions of low oxygenation that are apparent in the 1-h oxygenation image correlate quite closely with the regions of the flap which go on to fail over the intervening 72 h. The 1-h visual image of the flap shows no sign of trouble.

NIR spectroscopy provides a nonsubjective means of classifying the changes in the optical properties of tissue which are characteristic of tissue compromise. Spectroscopic methods offer the promise of detecting and distinguishing these characteristic changes prior to the appearance of overt clinical signs of tissue health or failure. Thus, spectroscopic analysis potentially enables earlier detection of perfusion related complications thereby allowing prompt and effective intervention. NIR spectroscopic assessment of skin injury, cutaneous wounds and burns as well as surgically reconstructed areas of tissues should potentially be able to provide the clinician diagnostic information early in the clinical time course. Early and reliable diagnosis of perfusion and oxygenation related complications in tissue near the surface of the skin should improve clinical management of these tissues when compromised and thereby improve patient outcome.

6 SUMMARY AND OUTLOOK

NIR spectroscopy is being applied to diverse areas of physiology and medicine to study the dynamics of tissue and muscle oxygenation, mitochondrial oxygen utilization and edema or desiccation in living systems. Medical applications of the technique are developing rapidly and the clinical utility of the method will undoubtedly continue to grow in the future. However, as pointed out throughout this review, practitioners of in vivo NIR spectroscopy are faced with a number of tantalizing technical challenges and a myriad of confounding variables that can influence the measurements and complicate interpretation of the data. For instance, the goal of providing a quantitative and/or semiquantitative analysis on the chromophores present in the tissue, noninvasively using NIR spectroscopy remains illusive. In vivo measurement of mitochondrial oxygen utilization based on the differential NIR absorption of reduced and oxidized cytochrome c oxidase has also proven to be a difficult obstacle. Correlating changes in the bulk scattering properties of the tissue to morphological or structural changes in the tissue is hampered by the variety of confounding factors that influence light attenuation measurements made on living tissues. While there is little doubt that clinically useful information is, in principal, latent in the NIR attenuation spectrum of tissue, extracting this information reliably remains the major challenge in further expanding the clinical role of in vivo NIR spectroscopy.

1 Introduction

Optical coherence tomography (OCT) is a technique with which to peer inside a body noninvasively. Tissue structure defined by tissue absorption and scattering coefficients, and the speed of blood flow, are derived from the characteristics of light remitted by the body. Singly backscattered light detected by partial coherence interferometry (PCI) is used to synthesize the tomographic image coded in false colors. A prerequisite of this technique is a low time-coherent but high space-coherent light source, usually a superluminescent diode or a multimode semiconductor laser. This limits the wavelengths to the red and near-infrared (NIR) region from about 600 nm to 1300 nm, the so-called therapeutic window, where absorption ($\mu_a \approx 0.01 \text{ mm}^{-1}$) is small enough. Transverse resolution in OCT is diffraction limited, as in conventional imaging; depth resolution is limited by the coherence length of the light. Both figures are of the order of micrometers. Velocity resolution is of the order of 0.1 mm s$^{-1}$. A few instruments are commercially available. At present, OCT is mainly used in the medical field, in particular in ophthalmology. Owing to the high transmissivity of ocular media, the depth penetration is considerable. Corresponding applications in dermatology are somewhat hindered by the strong scattering of epidermic tissue ($\mu_s \approx 10^2 \text{ mm}^{-1}$). As OCT provides images with a resolution comparable to conventional histology, but in real time, it can be used as a biopsy technique in a wide range of biological systems to detect diseases. These include the tomographic imaging of the internal microstructure of in vitro atherosclerotic plaques, the tomographic real-time diagnostics for intraoperative monitoring, and in microsurgical intervention. Optical biopsy based on OCT also provides diagnostic information by differentiating the architectural morphology of urological tissue, gastrointestinal tissue, and respiratory tissue.

1 INTRODUCTION

Tomographic imaging techniques derive a slice image from the internal structure of a three-dimensional object. Tomographic imaging has a long association with X-ray diagnostic radiology. Early X-ray techniques used a moving X-ray source, together with a detector that moved so that only the selected plane of interest was imaged sharply. Out-of-focus planes were blurred. Modern tomographic techniques, such as computed tomography (CT), use mathematical techniques to generate the tomographic image from a series of discrete projections. Tomographic imaging is performed with various types of radiation. The approach used to derive the slice image depends largely on the type of interaction of the radiation with the object. If X-rays or $\gamma$-rays are used as probes, straight-ray propagation can be assumed. Then the well-known projection technique (still commonly used in CT scanners but not so common in nuclear magnetic

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
resonance (NMR) scanners) can be used to obtain the tomographic picture from straight-ray projections. Absorption and scattering lead to severe attenuation and diffusion of the radiation and the applicability of this concept is limited. Furthermore, if the structural elements to be resolved are of the order of the radiation wavelength, diffraction has to be taken into account, at least in principle.

Optical tomography techniques have been developed intensively since the early 1980s.\(^{(1)}\) In optical tomography, tissue absorption and scattering coefficients are derived from the characteristics of light scattered and/or diffracted by the object. Three basic optical tomography approaches have been developed: (1) diffraction tomography,\(^{(2)}\) reconstructing the object structure from the corresponding diffraction pattern; (2) diffuse optical tomography,\(^{(3)}\) deriving spatial maps of absorption and scattering coefficients from the characteristics of multiply scattered light transmitted through the body; and (3) OCT,\(^{(4,5)}\) where these data are derived from backscattered light detected by PCI. Instruments based on diffuse optical tomography are under development. Some instruments based on OCT are commercially available.

Optical tomography has, on the one hand, the important properties of being nonionizing and, at visible and NIR wavelengths, being strongly influenced by tissue chromophores and thus being related to the health status of the tissue. On the other hand, biological tissues are strongly absorbing and scattering media, and the penetration depth of optical radiation is small. Only at the spectral region from about 600 nm to 1300 nm are the absorption and scattering small enough to form the so-called therapeutic window\(^{(6)}\) (Figure 1), which can also be used for OCT. Despite the rather small absorption coefficient of soft tissue (\(\mu_a \approx 0.01 \text{ mm}^{-1}\)) scattering is high (\(\mu_s \approx 10^2 \text{ mm}^{-1}\)) and therefore photons mainly propagate in a diffusive mode.

Light transmitted through tissue comprises ballistic, snake, and diffusive photons (Figure 2).\(^{(9)}\) Ballistic photons are unscattered photons or photons strictly forwards-scattered. Snake photons are scattered along a path close to a straight line. Ballistic and snake photons obey Beer’s law. Diffusive photons propagate in a random mode and obey the radiative transport equation.

Ballistic and snake photons of a light-pulse-transmitting tissue arrive at the exit surface first. These forward-propagating photons have a more or less deterministic path and, therefore, carry image information. Most optical forward-scattering tomography techniques under development rely on these image-bearing photons. Several gating techniques have been developed to isolate these photons from the usually more numerous diffuse photons. For example, a high-speed opto-electronic shutter can be used to separate the early ballistic and snake photons and to block the diffusive photons. Other examples are Fourier gates, coherence gates, polarization gates, nonlinear optical effects, and holographic techniques.\(^{(10)}\)

Unscattered photons can be used to obtain straight-ray projections. The mathematical problem of reconstructing a function from its straight-ray projections was first presented by J. Radon in 1917.\(^{(11)}\) Its solution, the Fourier slice theorem, shows that some three-dimensional Fourier data from an object can be obtained from a two-dimensional Fourier transform of the projection. Because of its similarity to the Fourier diffraction theorem,\(^{(11)}\) a closer look at this theorem is merited. From the Fourier transform (Equation 1) of the object function \(F(x, y, z)\) (which, for example, in X-ray CT characterizes the two-dimensional distribution of the linear X-ray attenuation
Figure 3 OCT arrangement. A partial coherence interferometer is used to perform optical A-scans along adjacent paths for a series of different $x$ positions at the object. The tomographic image is synthesized from backscattered light data obtained with the interferometer.

\[ \hat{F}(u, v, w) = \text{FT}[F(x, y, z)] = \int F(x, y, z) \times \exp[-2\pi i(ux + vy + wz)] \, dx \, dy \, dz \]  

it follows readily that the projection $P(x, y) = F(x, y, z)$ $\text{d}z$ has the two-dimensional Fourier transform of Equation (2):

\[ \text{FT}_{x,y}[P(x, y)] = \left\{ F(x, y, z) \, \text{d}z \right\} \exp[-2\pi i (ux + vy)] \, dx \, dy = \hat{F}(u, v, 0) \]  

Hence, some of the Fourier data of the object ($\hat{F}(u, v, 0)$) can be obtained from a Fourier transform of projections. In the CT technique, a series of such projections at different directions is used to obtain depth resolution. A filtering step is applied to correct for the radial dependence of the Fourier data density introduced by the projection procedure.\(^{(1)}\)

Diffuse photons do not propagate along straight rays. Several photon-transport models based on radiative transfer theory have been developed. A series of image-reconstruction algorithms has also been developed.\(^{(12)}\) However, image-reconstruction techniques for optical imaging through diffuse media remain at a preliminary stage of development.\(^{(13)}\)

OCT uses backscattered ballistic and snake photons. At present, its main application is in the field of medicine, where it yields high-quality images in a series of applications. However, the thickness of normal human organs does not permit the use of transmitted ballistic photons or transmitted snake photons. OCT is limited to highly transparent objects, such as eye tissue and mucosal tissues, and uses light scattered backwards from object. OCT\(^{(14,15)}\) uses PCI\(^{(16)}\) to obtain so-called optical A-scans (a term borrowed from ultrasound technology). Optical A-scans obtained at a series of lateral locations are used to synthesize the tomographic image, as indicated in Figure 3.

2 PHYSICAL BASIS

2.1 Backscattering and Diffraction Tomography

In OCT the object is illuminated by a focused partially or low-coherent wave. In the context of OCT, the terms low coherence and partial coherence mean low time coherence but high space coherence. Low coherent light beams are usually obtained from multimode laser diodes and superluminescent diodes. These light sources emit Gaussian beams in the fundamental transverse mode. The minimal transverse radius of a focused Gaussian beam occurs at the beam waist and is given by Equation (3):

\[ w_0 = \frac{\lambda}{\pi \theta} \]  

At this radius the beam intensity falls to $1/e^2$ of its central value.\(^{(17)}\) The variable $\theta$ is the asymptotic angle of beam divergence (or aperture). A characteristic length in beam propagation direction is the confocal beam parameter or Rayleigh length $z_0$. At this distance the transverse beam radius increases to $\sqrt{2}w_0$ (Equation 4):

\[ z_0 = \frac{\pi w_0^2}{\lambda} \]  

Figure 4 depicts a Gaussian beam illuminating the anterior part of an eye positioned at the beam waist. For simplification of the description the object depth is assumed of the order of the Rayleigh length of the illuminating beam. Then the illuminating light source wave has an approximately plane wavefront with wave
vector \( \mathbf{k}^{(i)} \). The electric field of the illuminating light source wave is represented as a complex scalar, i.e., polarization effects are ignored (Equation 5):

\[
E_{LS}(\mathbf{r}, t) = A_{LS} \exp(i\mathbf{k}^{(i)} \cdot \mathbf{r} - i\omega t) \tag{5}
\]

where \( A_{LS} \) is the light wave amplitude, \( |\mathbf{k}^{(i)}| = k = 2\pi/\lambda = w/c \) is the wavenumber, \( \lambda \) is the wavelength, \( w \) is the frequency, \( c \) is the velocity of light, and \( \mathbf{r} \) is the position vector. Let \( E_0(\mathbf{r}, t) \) be the electric field wave scattered by the object. The sum of the two waves \( E_{LS}(\mathbf{r}, t) + E_0(\mathbf{r}, t) \) satisfies the scalar Helmholtz equation. In the case of weakly scattering objects the scattered field can be obtained by the first Born approximation\(^{18} \) as a volume integral extended over the illuminated object volume (Equation 6):

\[
E_0(\mathbf{r}, t) = \frac{1}{4\pi} \int_{\mathcal{V}(r)} F_0(\mathbf{r'}) E_{LS}(\mathbf{r'}, t) G(|\mathbf{r} - \mathbf{r'}|) \, d^3\mathbf{r'} \tag{6}
\]

The Green’s function of the Helmholtz equation is given by Equation (7):

\[
G(|\mathbf{r} - \mathbf{r'}|) = \frac{\exp(ik^{(s)}|\mathbf{r} - \mathbf{r'}|)}{|\mathbf{r} - \mathbf{r'}|} \tag{7}
\]

Here \( k^{(s)} = |\mathbf{k}^{(s)}| = k \), where \( \mathbf{k}^{(s)} \) is the wave vector of the (coherently) scattered wave. Equation (6) can be considered as quantification of Huygens’ principle: the Green’s function represents the secondary wavelets which combine to form the scattered light. The term \( F_0(\mathbf{r}) \) is the scattering potential of the object, or the object structure. It determines the relative amplitudes and phases of the scattered wavelets (Equation 8):

\[
F_0(\mathbf{r}) = k^2[m^2(\mathbf{r}) - 1] \tag{8}
\]

where \( m(\mathbf{r}) \) is the complex refractive index of the object. In general, \( m \) will depend on the wavelength \( \lambda \); here, \( m \) is assumed to be isotropic and independent of the wavelength. Furthermore, because in OCT the object is illuminated by a rather narrow light beam (\( w_0 \ll L \) in Figure 4), far-field scattering is a reasonable approximation. In this case the exponent in \( G \) can be expressed as in Equation (9)\(^{19} \):

\[
-ik^{(s)}|\mathbf{r} - \mathbf{r'}| = ik^{(s)}(\mathbf{r} - \mathbf{r'}) \tag{9}
\]

Equation (6) then yields Equation (10),

\[
E_0(\mathbf{r}, \mathbf{K}, t) = \frac{A_{LS}}{4\pi L} \exp(i\mathbf{k}^{(s)} \cdot \mathbf{r} - i\omega t) \times \int_{\mathcal{V}(r)} F_0(\mathbf{r'}) \exp(-i\mathbf{K} \cdot \mathbf{r'}) \, d^3\mathbf{r'} \tag{10}
\]

where \( \mathbf{K} = \mathbf{k}^{(s)} - \mathbf{k}^{(i)} \) is the scattering vector. The wave scattered by the object is modified by the Fourier transform of the scattering potential of the object.\(^{20} \) The Fourier variable in the frequency domain is \( 2\omega/\lambda \). This is the far-field version of the Fourier diffraction theorem.\(^{1} \) The variable \( L \) is the distance of the detection point \( P \) at position \( r_P \) from the origin near the object. Hence, the three-dimensional scattering potential \( F_0(\mathbf{r}) \) can be obtained from the scattered field \( E_0(\mathbf{r}, \mathbf{K}, t) \) by an inverse Fourier transform. This is the physical basis of diffraction tomography.\(^{21} \) Diffraction tomography is still in a rather immature state. A simplified one-dimensional version, however, is used in the optical A-scan of OCT.

There are some limitations in diffraction tomographic imaging, which also pertain to OCT (and other related imaging techniques). These can be seen from the data geometry in \( \mathbf{K} \)-space, Figure 5. A general three-dimensional object will have Fourier data in a certain volume centered, for example, at the origin 0 of \( \mathbf{K} \)-space. For any direction of the scattered light the scattering vector \( \mathbf{K} \), however, points onto the surface of the so-called Ewald sphere.\(^{21,22} \) Only these Fourier data are available by scattering. Using a wavelength range from \( \lambda_1 \) to \( \lambda_2 \) gives access to Fourier data between the corresponding Ewald spheres.

The situation is even worse in the OCT A-scan. Here, backscattering along the illumination axis is used. If a wavelength range from \( \lambda_1 \) to \( \lambda_2 \) is used, Fourier components of the scattering potential in a high spatial frequency range (\( K_{1z}, K_{2z} \)), indicated by BS in Figure 5, can be accessed. Hence, only relatively abrupt changes in the scattering potential, occurring within a few wavelengths, can be seen by backscattering tomography. Therefore, OCT is a high-pass imaging technique.

For further simplification, we replace the integrations over \( x' \) and \( y' \) in Equation (10) by a constant factor \( W \),
chosen proportional to the cross-section of the beam waist of the illuminating beam. Then the A-scan field backscattered by the object along the illumination axis at point $P$ (namely $k^{(0)} = -k^{(s)}$; $|k^{(0)}| = |k^{(s)}| = k$) is

$$E_0(P, k, t) = \frac{A_{LS} W}{4\pi L} \exp(-ikz - iwt)$$

$$\times \int_{D} F_0(z') \exp[iKz'] \, dz'$$

With $K = 2k = |K|$. Equation (11) is the physical basis of Fourier domain OCT. The (complex) amplitude of the backscattered A-scan wave equals the (inverse) Fourier transform of the object structure.

Equation (11) can also be written in terms of a convolution (Equation 12):

$$E_0(z, k, t) = \frac{A_{LS} W}{4\pi L} \exp(-ikz - iwt)$$

$$\times \int_{D} F_0(z') \exp[2ikz'] \, dz'$$

$$= \frac{A_{LS} W}{8\pi L} \int_{0}^{2D} F_0 \left( \frac{z'}{2} \right)$$

$$\times \exp[-ik(z - z') - iwt] \, dz'$$

This is a spatial convolution of the twofold dilated object structure with a backtraveling light wave (Equation 13):

$$E_0(z, k, t) \propto F_{0(1/2)}(z) \otimes E_B(z, k, t)$$

with (Equation 14)

$$E_B \propto A_{LS} \exp(-ikz - iwt)$$

Here the convolution notation of Equation (15) has been used:

$$f(t; p) \star g(t; p) = \int_{-\infty}^{+\infty} f(t; p)g(t - \beta x; p) \, dx$$

$$= \int_{-\infty}^{+\infty} f(t; p)g(t - \beta x; p) \, dx$$

Equation (13) is the basis of time-domain OCT. The backscattered A-scan wave equals the reflected light source wave convolved with the scattering potential of the object. Because of the twofold transit of the light, the $z$-extension of the scattering potential has to be enlarged by a factor of 2.

### 2.2 Time-domain and Fourier-domain Optical Coherence Tomography

#### 2.2.1 Time Domain

In time-domain OCT the object structure encoded in the A-scan wave is deciphered with the help of a reference wave (Figure 6). The wave remitted by the object is brought to interference with a low-coherence reference wave traveling back from the reference mirror (Equation 16):

$$E_R(z, k, t) \propto A_{LS} \exp(-ikz - iwt)$$

Thus, the resulting field strength is the sum of the object and reference waves (Equation 17):

$$E(z, k, t, \tau_R) = E_0(z, k, t) + E_R(z, k, t + \tau_R)$$

Where a delay $\tau_R = 2(d - s)/c$ between the two waves has been assumed.

The light intensity is defined as the cycle-averaged Poynting vector of the corresponding electromagnetic energy density:

$$I = \frac{1}{2} \text{Re} \left[ E \star H^* \right]$$

**Figure 6** Michelson interferometer configuration for time-domain OCT. The A-scan is performed by scanning the time delay $\tau = (s - d)/c$ with the help of the reference mirror.
where, however, light waves used in OCT are not monochromatic but are quasimonochromatic waves with statistical properties and should be treated as stochastic processes. This means that observables should be defined as ensemble averages. Usually, these ensemble averages can be replaced by time averages over many cycles of the corresponding observable; therefore, the light intensity is given by Equation (18)

\[
I = \frac{1}{2} \varepsilon_0 c n^2 \left( \frac{T}{2} \right) E^*(t)E(t) dt
\]

\[
= \frac{1}{2} \varepsilon_0 n (E^*(t)E(t))
\]

(18)

where \( T \gg 2\pi/w \), \( \varepsilon_0 \) is the electric permittivity, \( c \) is the velocity of light, and \( n \) is the phase refractive index.

Time-domain OCT is based on the transit time of wave groups. Wave groups show specific propagation properties. Their phase velocity equals the (phase) velocity of the corresponding carrier wave, whereas the amplitudes propagate with the group velocity. The reference wave is a backscattering wave directly derived from the light source wave by a beam splitter and reflection at the reference mirror (Equation 19):

\[
E_R(t) = \alpha E_B(t)
\]

(19)

where \( \alpha \) is a constant depending on the properties of the beam splitter and the reference mirror. The object wave is also a backscattering wave: \( E_B \) convolved with the scattering potential of the object (Equation 13). This convolution introduces a time delay \( t_0 \) (Equation 20):

\[
t_0 = \frac{\Delta z n G}{c}
\]

(20)

where \( n_G \) is the group index and \( \Delta z \) is the additional pathlength introduced by the object.

Hence, the object wave (Equation 21) is

\[
E_0(t) = \int_0^{2D} F_{01/2}(t-\tau)E_B(\tau) d\tau = F_{01/2}(t) \otimes E_B(t)
\]

(21)

The desired information is contained in the mutual coherence function of the re-emitted object wave and the reference wave in the interferometer term. Assume that the pathlengths of the reference beam and the object beam are matched. Then the intensity at the interferometer exit is (Equation 22)

\[
I_E(t) = \frac{1}{2} \varepsilon_0 c (|E_R + E_0|^2) = I_R + I_0 + \alpha \varepsilon_0 c \text{Re}(E_B(t)E_0(t + \tau))
\]

(22)

Using the commutative law of convolution yields Equation (23):

\[
I_E(t) = \frac{1}{2} \varepsilon_0 c (|E_R + E_0|^2) = I_R + I_0 + \alpha \varepsilon_0 c \times \text{Re}(E_B(t)E_0(t + \tau))
\]

(23)

The time average \( \langle \cdot \rangle \) depends on the time coherence function \( \Gamma_{LS}(\tau) \) or the complex degree \( \gamma_{LS}(\tau) \) of coherence of the source wave (Equation 24):

\[
\langle E_B(t)E_B^*(t + \tau) \rangle = I_B \Gamma_{LS}(\tau)
\]

(24)

with (Equation 25)

\[
\gamma_{LS}(\tau) = \frac{\langle E_B^{2*}(t)E_{LS}(t + \tau) \rangle}{\langle E_{LS}(t)E_{LS}(t + \tau) \rangle} = \frac{I_B}{I_{LS}}
\]

(25)

Hence, besides being a constant factor, the interferogram term is the real part of the convolution of the object structure with the complex degree of the time coherence (Equation 26):

\[
I_E(t) = \frac{1}{2} \varepsilon_0 c (|E_R + E_0|^2) = I_R + I_0 + \alpha 2 \varepsilon_0 c \times \text{Re}(E_{LS}(\tau) \otimes F_{01/2}(t))
\]

(26)

Therefore, the object structure along the A-scan is obtained by scanning the time delay \( \tau \) with the help of the reference mirror. The complex degree \( \gamma_{LS}(\tau) \) of the time coherence plays the role of a longitudinal or depth point spread function.

If the object is a single reflecting plane at \( z_0 \), this gives (Equation 27)

\[
I(\tau) = I_0 + I_R + 2 \sqrt{I_R} \text{Re}(\gamma_{LS}(\tau))
\]

(27)

Therefore, in PCI the complex degree \( \gamma_{LS}(\tau) \) of the time coherence plays the role of a longitudinal or depth point spread function.

2.2.1 Dispersion

Most A-scans are performed through dispersive media, whereas the reference beam travels, for example, through air. Then the Fourier components of the A-scan wave and the reference wave experience different time delays and the two waves decorrelate. Hence, the complex degree \( \gamma_{LS}(\tau) \) of the time coherence broadens and the resolution decreases. If the length of a dispersive medium in one of the interferometer arms is \( L \) and the group dispersion of the medium is \( d n_G / d \lambda \), the width of the coherence envelope, after double passing through the medium, is given by Equation (28):

\[
l_{c,m} = l_c + \left( \frac{d n_G}{d \lambda} 2 L \Delta \lambda \right)^{1/2}
\]

(28)
Optimum resolution is achieved by placing a dispersion-compensating plane-parallel plate in the longer interferometer arm.

### 2.2.2 Fourier Domain: Complex Spectral Optical Coherence Tomography

In Fourier domain OCT the object structure can be obtained by several techniques. The most straightforward technique is to detect the (complex) K-spectrum of amplitude and phase data of the scattered field (Equation 11). The object structure is then obtained from an inverse Fourier transform (Equation 29):

\[ F_0(z) \propto \text{FT}^{-1}[E_0(P, K)] \tag{29} \]

The K-spectrum of the light backscattered in an A-scan can be obtained with the help of an interferometric spectrometer. This device is a spectrometer with phase-measuring capability (provided by the interferometer) as depicted in Figure 7.

In the interferometric spectrometer a detector array is used at the focal plane of the spectrometer optics. Known phase changes are induced between the object and reference beam by shifting the reference mirror by fixed amounts. From the spectral intensity data at the interferometer exit obtained at these reference mirror positions the spectral object wave phase and its intensity can directly be calculated. Several algorithms are known that calculate the phase of a light wave using this technique; these algorithms also compensate phase-shift miscalibration and detector nonlinearity.

![Figure 7](image-url)

**Figure 7** Fourier domain OCT with a Michelson interferometric spectrometer. \(U_{PE}\) is the piezoelectric driving voltage used for phase measurement.

#### 2.2.3 Fourier Domain: Spectral Interferometry Optical Coherence Tomography

In this technique the light exiting from the interferometer is detected by a photodetector array at the exit plane of a spectrometer in a similar way as in the complex interferometry technique. However, only the spectral intensity is recorded. No spectral phases are measured. Hence, a Fourier transform of the measured data does not yield the object structure but its autocorrelation. However, autocorrelation is not reversible. To obtain the object structure there are two possibilities. First, an additional singular light-remitting interface (reference mirror) is positioned at an optical path difference \(z_R\) from the object. Second, the object scattering potential can also be obtained if the object itself contains one interface with a relatively large reflectivity \(R\) acting as a reference mirror. In both cases the scattering potential can be described as a sum of the object structure \(F_0(z)\) plus a delta-like potential at \(z_R\) (with amplitude reflectivity \(R\); Equation 30):

\[ F(z) = F_0(z) + R\delta(z - z_R) \tag{30} \]

and the autocorrelation yields four terms (Equation 31):

\[
\begin{align*}
(F^*F)(z + Z) &= \langle F_0^*(z)F_0(z + Z) \rangle \\
&= \langle F_0^*(z)R\delta(z + Z - z_R) \rangle \\
&= \langle R\delta(z - z_R)F_0(z + Z) \rangle \\
&= \langle R^2\delta(z - z_R + Z) \rangle \\
&= \text{ACFF} + R\text{RF} + R^2\delta \tag{31}
\end{align*}
\]

An overlap between the four terms of the autocorrelation can be avoided by choosing the distance between the reference mirror and the object larger than the object depth \(D: |z_R| > D\). Then the third term of Equation (31) yields a reconstruction of the object structure, centered at \(Z = -z_R\).

#### 2.2.4 Fourier Domain: Chirp Optical Coherence Tomography

Chirp OCT (the name comes from the early days of the related electronic radar technique, when a sound produced by a pulse resembled the chirps of a bird in song), or wavelength tuning OCT uses the tunable laser interferometry technique. Here the wavelength is tuned over a range of wavenumbers and the spectral light intensity remitted from the object is detected. Whereas in the spectral interferometry technique the intensity spectrum is simultaneously recorded by the detector array, here the same data are recorded sequentially by a single photodetector.
2.3 Doppler Optical Coherence Tomography

This technique combines OCT with Doppler velocimetry.\(^{(31)}\) Doppler velocimetry detects the frequency shift \(w_D\) in the light scattered by moving particles (Equation 32):

\[
w_D = (k^{(s)} - k^{(i)}) v = Kv\tag{32}
\]

where \(v\) is the velocity of the moving particle. A frequency shift in the object beam leads to an additional phase term \(f(t) = \exp(iw_Dt)\) (Equation 33):

\[
E_0(t) = f(t)E_B(t)\tag{33}
\]

The intensity at the interferometer exit, with the reference field strength \(E_B(t)\), is given by Equation (34):

\[
I(t) \propto \langle |E_B(t) + E_0(t + \tau)|^2 \rangle
\]

\[
\propto I_R + I_0 + 2\text{Re}\{E_B^*(t)E_0(t + \tau)\}\tag{34}
\]

The frequency-dependent intensity or power spectrum is obtained from the Fourier transform of the correlation function of the electric fields (Equation 35):

\[
I(w) \propto \text{FT}\{\langle E_B^*(t)E_0(t + \tau)\}\}
\]

\[
= \text{FT}\{f(t)E_B^*(t)E_0(t + \tau)\}
\]

\[
= \hat{f}(w) \otimes S(w)\tag{35}
\]

where \(\hat{f}(w)\) is the spectrum of the light scattered by the moving particles and \(S(w)\) is the power spectrum of the source light.

2.4 Spectroscopic Optical Coherence Tomography

One of the most powerful spectrometric techniques is Fourier spectrometry. This technique relies on the Fourier relationship between the frequency-dependent spectrum of a light beam and its first-order electric field correlation function (Equation 36):\(^{(23)}\)

\[
I_0(w) = \frac{1}{2}	ext{sgn}\text{FT}\{\langle E_0^*(t)E_0(t + \tau)\}\}	ag{36}
\]

To use this technique in OCT the complete A-scan signal must be recorded. No rectification or low-pass filtering must be used. This signal has then to be split into series of small time windows. Within each time window a Fourier transform yields the optical spectrum of the back-scattered light. The corresponding depth positions are obtained in the usual way.

2.5 Resolution

2.5.1 Optical Coherence Tomography Depth Resolution

In time-domain OCT the complex degree \(\gamma_{LS}(t)\) of the time coherence plays the role of a longitudinal or depth point spread function (Equation 26). For example, most of the light sources used in OCT at present have an approximately Gaussian frequency spectrum. Therefore, they also have an approximately Gaussian degree of coherence (Equation 37),\(^{(23)}\)

\[
\gamma_{LS}(t) = \exp\left(-i\omega_0\tau - \frac{1}{2}\delta^2\tau^2\right)\tag{37}
\]

with the full width at half-maximum (fwhm) value or coherence time \(\tau_C = 1.17\pi/\delta\), and the longitudinal coherence length \(l_C = c\tau_C\) (Equation 38):

\[
l_C = \frac{4\ln2\lambda_0^2}{\pi\Delta\lambda}\tag{38}
\]

where \(\lambda_0\) is the mean wavelength and \(\Delta\lambda\) is the wavelength fwhm. In OCT, however, where the light travels along the same path twice (back and forth through the object) the depth resolution \(\Delta z\) is given by Equation (39):

\[
\Delta z = \frac{l_C}{2} = \frac{2\ln2\lambda_0^2}{\pi\Delta\lambda}\tag{39}
\]

For example, superluminescent diodes at a mean wavelength \(\lambda_0 = 830\text{ nm}\), have spectral widths of about \(\Delta\lambda = 25\text{ nm}\). Thus a corresponding coherence length of \(l_C = 24\mu\text{m}\) and a depth resolution of approximately 12\(\mu\text{m}\) are obtained.

Depth resolution in Fourier domain OCT can be estimated with the help of the Fourier uncertainty relationship. For a Gaussian spectrum the fwhm values \(\Delta z\) and \(\Delta s\) of the Fourier variables are related by Equation (40):

\[
\Delta z\Delta s = \frac{4\ln2}{\pi}\tag{40}
\]

With \(s = 2/\lambda\) the same relationship as in time-domain OCT is obtained.

2.5.2 Optical Coherence Tomography Transverse Resolution

In imaging optics, transverse resolution is usually defined by the Rayleigh criterion. Two object points are resolved if the center of the transverse point spread function (Airy disk) of one object point falls on the first zero of the point spread function generated by the second.\(^{(32)}\) Most beams used in OCT are approximately Gaussian beams in their fundamental transverse mode. In this
case, however, there is no zero intensity. If the transverse sampling rate is high enough, i.e. if it satisfies the sampling theorem, transverse resolution in OCT is determined by the transverse width of the beam performing the coherence scan. High transverse resolution demands that the beam is focused to a small beam waist radius $w_0$. This is the radius at which the beam intensity falls to $1/e^2$ of its central value. The minimal transverse separation of two resolved image points is of the order of this value. Hence (see Equation 3), $w_0$ can be used to define the minimal transverse separation $\delta$ resolved in OCT (Equation 41):

$$\delta = \frac{\lambda}{\pi \vartheta}$$  \hspace{1cm} (41)

A small beam waist radius demands a large asymptotic angle $\vartheta$ of beam divergence, but a high divergence results in a reduced confocal beam parameter $z_0$. Twice the confocal beam parameter can be used to define the depth of focus (DOF) (Equation 42):

$$\text{DOF} = 2z_0 = 2\frac{\pi w_0^2}{\lambda}$$  \hspace{1cm} (42)

Therefore, a compromise has to be found between the desired DOF and the desired transverse resolution $\delta$. For example, a transverse resolution of $\delta = 20\mu m$ at a mean wavelength of $\lambda_0 = 830\text{ nm}$ leads to a DOF of 3 mm, whereas a transverse resolution of $\delta = 2\mu m$ reduces the DOF to only 30 $\mu m$.

The resolution arguments discussed above apply to all the OCT techniques described in this article.

3 OPTICAL COHERENCE TOMOGRAPHY SCHEMES

3.1 Reflectometer Optical Coherence Tomography

Many PCI techniques have been described. PCI has been used for many years to measure the thickness of thin films, as a position sensor, and to measure other features that can be converted to a displacement. At present all OCT techniques use PCI to perform the A-scan.

The standard PCI technique is depicted in Figure 8. The A-scan is performed by moving the reference mirror at constant speed. Interference bursts occur at the interferometer exit, if any pathlength to a light-remitting site in the object arm coincides (within the coherence length) with the pathlength in the reference arm.

An alternating current (AC) signal $U$ is detected at these positions by the photodetector, which has the Doppler frequency corresponding to the speed of the reference mirror. Therefore, noise-reducing electronic AC techniques can be used to obtain high signal quality.

Amplification followed by band-pass frequency filtering, rectification, and low-pass frequency filtering is normally used to obtain the electronic interferometer signal $S$. This signal can either be used to determine distances between object interfaces or as the basic PCI depth scan signal for OCT.

At present, reflectometer OCT is by far the most frequently used OCT technique. One disadvantage of the reflectometer technique is that the reference mirror has to be shifted along the whole optical length of the object. However, as living samples move, the reference mirror is moved at high speed to avoid erroneous measurements. A more basic solution to this problem is the dual-beam technique. In this technique a path difference generated in the interferometer is matched to the path difference in the object. Hence the measurement becomes more or less insensitive to object movements.

3.2 Dual Beam Optical Coherence Tomography

In this technique the object is illuminated by both beams exiting from a Michelson interferometer (or other two-beam interferometer). The interferometer splits the beam exiting from the light source into two components $E$ and $E'$, generates a path difference, and recombines the two components. One of the interferometer mirrors is moved by a stepper motor with a constant speed $v$, which causes a Doppler shift $f_D = 2v/\lambda$ of the light frequency of one beam component. The recombined beam leaves the...
Figure 9 Dual-beam OCT: $U$ is the electric photodetector signal, $S$ is the interferometer A-scan signal. The A-scan is performed by moving the measurement mirror (MM) at constant speed, thus matching the path difference $z$ of the Michelson interferometer to distances between light remitting sites of the object. $E_F$ and $E'_F$ are subcomponents remitted by the eye’s fundus; $E_C$ and $E'_C$ are subcomponents remitted by the cornea.

interferometer as a coaxial dual beam. A lateral scanning mirror directs the dual beam to transversely adjacent positions at the object. Each of the two components $E'_F$ and $E_F$ of the dual beam that leave the interferometer towards the object generate subcomponents reflected at the object interfaces, separating regions of different refractive indices in the object. If the interferometer arm length difference coincides with an object interface distance, an interference burst occurs at the photodetector at a frequency $f_D$. The photodetector signal is amplified and filtered by a band-pass filter that transmits only signals with $f_D$. The envelope of the rectified signal ($S$ in Figure 9) is the final A-scan signal and is recorded as a function of the interferometer’s arm length difference $z$ and azimuthal position by a personal computer.

The dual-beam scheme has the advantage of being relatively insensitive to object movements. It needs, however, a reference interface with high reflectivity.

3.3 Enface Optical Coherence Tomography

OCT generates depth images, i.e. images in planes normal to the object surface. Enface OCT generates transverse images. These images can be obtained by fixing the reference mirror and transversely scanning either the object or the sample arm of the interferometer. A corresponding arrangement has also been described by Podoleanu et al. Their experimental arrangement used a single-mode directional coupler, where the output fibers form a Michelson interferometer. The reference arm consists of a fixed microscope objective and a mirror mounted on a micrometer scanning stage. The sensing arm contains a microscope objective collimating the beam exiting from the fiber. A bidirectional galvanometer-driven scanner is used to transversely scan the target. Scanning the light beam across the (plane) target surface leads to a modulation of the corresponding pathlength and thus to a frequency modulation of the photoelectric signal, similar to that generated by the PCI depth scan.

A disadvantage of this technique is that, owing to the nonlinear pathlength dependence on the scanning angle, a frequency spread of the photoelectric signal occurs leading to a reduced signal-to-noise ratio. This disadvantage can be overcome by either frequency shifting the reference beam or laterally displacing the target beam from the axis of rotation of one of the galvanometer-driven mirrors, which leads to an additional modulation that is essentially linearly dependent on the deflection angle (Figure 10).

3.4 Dynamic Coherent Focus Optical Coherence Tomography

In contrast to conventional optical imaging, in OCT the depth or longitudinal resolution and transversal
resolution are uncoupled. OCT depth resolution is determined by half the coherence length $l_C$ of the light used, whereas OCT transverse resolution, as for transverse resolution in lens optics, is limited by the aperture of the imaging light beam. Most OCT techniques generate depth tomograms (i.e. sections perpendicular to the object surface). Hence, it is not only the transverse resolution that counts but also the DOF (section 2.5). The DOF versus transverse resolution $w_0$ is nonlinear (Equation 42).

In order to maintain high transverse resolution throughout a reasonable object depth, the focusing lens can be shifted synchronously with the reference mirror during the depth scan. However, this involves the (rapid) movement of at least two optical components. Alternatively, the dynamic coherent focus technique can be used, which only needs one moving mirror. The optical principle is depicted in Figure 11.

The probing beam of a reflectometer or dual beam device is focused to a first focus by lens 1 at an oscillating mirror, positioned near the focal plane of another lens 2. The oscillating mirror performs the A-scan. The beam leaving lens 2 is turned round by a scanning unit (scanning mirror 2) and focused by lens 3 to the dynamic coherent focus within the object. By choosing the focal lengths of lenses 2 and 3, a preselected shift of the dynamic focus within the object can be realized.

Focusing the probing beam through a medium with a refractive index different from that of air causes an additional pathlength mismatch. First, the focus formed within the object is shifted by refraction at the interface between the air and the object (with phase refractive index $n$). Second, in OCT the optical pathlength in a medium equals the geometrical pathlength multiplied by the group refractive index $n_G$. Hence, the dynamic focus is at an optical depth given approximately by Equation (43):

$$z'' = n n_G z$$

### 3.5 Doppler Optical Coherence Tomography

Two schemes have been used to obtain OCT maps of flow. In the so-called optical Doppler tomography (ODT) technique the lateral scans are performed with a constant velocity, followed by an incremental probe movement in the axial direction. In the so-called color Doppler optical coherence tomography (CDOCT) technique the usual OCT scan mode is used, i.e. axial A-scans are performed at laterally adjacent locations.

#### 3.5.1 Optical Doppler Tomography

In the ODT technique the light from the superluminescent diode and an aiming He–Ne laser beam are coupled into a fiber interferometer using a $2 \times 1$ coupler and then split equally into reference and target arms by a $2 \times 2$ fiber coupler (Figure 12). Piezoelectric transducer optical delay lines are used to modulate the optical

![Figure 10](image_url)  
**Figure 10** Optical scheme of enface OCT. The A-scan is performed by one of the galvo scanners in a direction (for example, the $x$ direction) transverse to the illuminating beam. The scan depth is adjusted by the reference mirror.

![Figure 11](image_url)  
**Figure 11** Dynamic coherent focus for enhanced depth of field OCT. The first focus is imaged by lenses 2 and 3 onto the object.

![Figure 12](image_url)  
**Figure 12** Diagram of ODT. Tomograms are formed from sequential lateral scans in the $x$ direction followed by probe movement in the $z$ direction.
phase of the reference and probing beams. The probing beam is focused onto the sample by a gradient index lens with the optical axis oriented at 15°–20° to the normal of the flow velocity (otherwise the Doppler shift vanishes, see Equation 32). Tomographic images are formed by laterally scanning the sample in a transversal direction followed by a sample movement in the z direction between the lateral scans. The interference fringe intensity at the interferometer exit is detected by a photodetector. After analog-to-digital conversion a short-time fast Fourier transform of the photodetector signal yields a spectrogram. From the signal at the phase modulation frequency a tomographic structural image is obtained, whereas from the Doppler frequency shift the flow velocity is determined.

3.5.2 Color Doppler Optical Coherence Tomography

In this technique, as in time-domain OCT, A-scans are performed at a series of laterally adjacent locations. Whereas in time-domain OCT the envelope of the interferometric signal is detected, CDOCT uses coherent detection of the interferometer signal. As in OCT the reference wave is Doppler frequency shifted by the constant motion of the reference mirror (Figure 13). The actual interferometric fringe frequency detected by the photodetector arises from the net sum of Doppler shifts generated by the moving reference mirror and moving scatterers in the sample. After band-pass filtering, coherent demodulation of the photodetector signal, and analog-to-digital conversion, short-time Fourier transform is applied for each depth scan. The resulting power spectra correspond to short-time sections of the A-scan. The local Doppler frequency is estimated from the centroid of each spectrum. The detected velocity is color coded to indicate magnitude and direction of flow.

Using a time-gating technique (periodic) dynamic changes in tissues have been recorded by CDOCT. For example, a series of frames of the beating heart of *Xenopus laevis* has been recorded. First, 1000 laterally oversampled A-scan OCT image with at least five A-scans per heartbeat was acquired while the sample was translated laterally. The frames were then composed from the 1000 A-scans obtained at different lateral positions but at the same segment of the cardiac cycle.\(^{39}\)

3.6 Endoscopic Optical Coherence Tomography

Essential to OCT imaging of internal organs is a catheter endoscope. In the OCT catheter endoscope depicted in Figure 14 light from the interferometer probing arm is coupled across a small air gap into the catheter optical fiber. The OCT catheter consists of a single-mode fiber attached to a focusing gradient index (grin) lens with a beam-directing microprism at the distal end, and an optical coupling element at its proximal end. Precise optical coupling between the two fibers is ensured by mounting the fibers in a precision mechanical ferrule assembly using two male fiber connectors and a male-to-male optical fiber coupler, typically used for rigidly connecting two fibers. The body of the catheter is composed of a flexible, rotating inner sleeve that fits loosely inside a stationary outer sheath. The optical fiber is fixed within the center of the inner sleeve, which is rotated as a unit with the optical connector.

4 IMPLEMENTATION

Only a few components specific to OCT are mentioned here.

4.1 Light Sources

Depth resolution as well as spectrometric resolution in OCT are determined by the spectral width of the light source. Table 1 shows some examples of spectral widths and coherence lengths of different light sources; most have already been used in OCT.

The ideal OCT light source would yield radiation with perfect space coherence but low time coherence. In terms of laser optics this radiation must only contain longitudinal modes. This requirement is not generally met by low-coherence lasers. At present the most promising light sources in OCT are SLD and mode-locked solid-state lasers. Thermal light sources yield extremely low time-coherence radiation but suffers from a corresponding low space coherence. Filtering out spatially coherent waves reduces the available power to a few microwatts.

4.2 Optical Delay Lines

Time-domain OCT requires the scanning of a reference group delay to acquire the A-scan data. As many A-scans (500 or more) are acquired per tomographic image, rapid optical delay lines are needed. Many technical solutions have been proposed. As the total optical pathlength modulation needed is of the order of some millimeters, most delay lines use a mechanical solution (Table 2).

The first optical delay lines used a reference mirror mounted on a stepper-motor-driven linear translation stage. Scanning velocities of these systems are limited to some 10 cm s⁻¹. For small scanning ranges piezoelectric actuators are suitable. However, their scanning range is limited to about 100 µm. Piezoelectric devices also suffer from drift and hysteresis.

Spinning glass cubes and spinning mirror pairs yield far higher scan velocities but suffer from a limited duty cycle. Spinning glass cubes introduce a delay-dependent dispersion. Spinning mirror pairs do not introduce dispersion. Moreover, a given dispersion in the collateral interferometer arm can be compensated by arranging a dispersion prism in front of the retroreflector, as indicated in Figure 15. High scan velocities and repetition rates can be achieved.

A standard optical delay line technique is a long fiber coiled around a cylindrical piezoelectric transducer used

![Figure 15](image-url)  
**Figure 15** Spinning mirror pair used as optical delay line. Different dispersion prisms in front of the retroreflector can be used for matching a desired dispersion independently from the pathlength delay.

SLD, superluminescent semiconductor diodes.
to stretch it. High-speed data acquisition and path delays of a few millimeters are possible. The drawbacks of this technique are birefringence, polarization mismatch by the fiber, drifts and hysteresis caused by the piezoelectric transducer, and the high voltage needed to operate the device.

A high-speed delay line with independent phase and group delay has been described by Tearney et al. From the Fourier shift theorem it follows that a linear phase ramp in the Fourier domain causes a delay in the time domain. Hence, a linear phase ramp is generated by placing a tilted mirror at the Fourier plane of a lens. Scanning the mirror angle produces a time-dependent optical group delay. Shifting the scanning mirror so that the center wavelength is offset from the axis of rotation generates an arbitrary heterodyne frequency (Figure 16).

High repetition rates can also be realized by oscillating devices such as galvanometer scanners. These devices can be operated with triangle waveforms at high frequencies (see Figure 11).

4.3 Optical Detectors

OCT signals from biomedical objects are weak. For low-light detection in the visible and NIR spectral range three basic detector technologies are available: the silicon (p-doped, intrinsic semiconductor, with n-doped layers) PIN photodiode, the silicon avalanche photodiode (APD), and the photomultiplier tube. Most OCT light sources operate in the red and NIR spectral region, where PIN diodes and APDs offer superior quantum efficiency, approximately two orders of magnitude larger than the photomultiplier tube. The internal gain of an APD can boost the signal above the noise of the preamplifier and/or the detector current. However, an improvement is realized only when preamplifier noise and dark-current noise are the limiting factor. If the signal is strong enough, the APD performs worse than the equivalent PIN diode.

5 APPLICATIONS

OCT has found manifold applications in medicine but only a few technical applications, such as tomographic imaging of the fiber architecture of glass-reinforced polymer composites and the detection of subsurface defects in ceramics. Compared to related imaging techniques such as confocal imaging, OCT has the advantage in that its depth resolution is independent of the aperture of the scanning light beam. Therefore, OCT is useful in cases where high depth resolution is required but only a limited aperture is available. Because the OCT image is constituted from the tissue reflectivity of an infrared (IR) beam, precautions are required to interpret the cross-sectional images. As light is strongly scattered in most tissues, the imaging depth of OCT is limited to a few millimeters. OCT yields depth images and can be used to image NIR-transparent objects, such as tissues of the eye (Figure 17) and mucosal tissues.

5.1 Ophthalmology

Ophthalmology is the main field of OCT applications in medicine. OCT has been used to perform direct imaging of the ocular structure in the anterior and posterior segments of human eyes in vitro and in vivo. OCT yields a cross-sectional image of the retina with a resolution comparable to a histological section in light microscopy. OCT can discriminate the cross-sectional morphological features of the fovea and optic disk. OCT was successful in staging macular holes and provided a quantitative measure of hole diameter and the amount of surrounding macular edema. OCT was also used to evaluate the vitreoretinal interface in a patient’s fellow eyes and was able to detect small separations
of the posterior hyaloid from the retina.\textsuperscript{58} Idiopathic juxtafoveal retinal telangiectasis\textsuperscript{59} and degenerative retinoschisis from retinal detachment\textsuperscript{60} have also been studied using OCT. The presence of a nonregular pattern of the retinal pigment epithelium was found by OCT in partial lipodystrophy.\textsuperscript{61} The high depth resolution of OCT that is available even at the eye’s fundus has been used to measure the thickness of fundus layers.\textsuperscript{55,57,62,63}

Animal experiments have been performed to elucidate the relationship between OCT scans and retinal histology. In a direct comparison of OCT and histological images of the Macaca mulatta macula, the OCT images demonstrated reproducible patterns of retinal morphology that corresponded to the location of retinal layers seen on light microscopic overlays.\textsuperscript{64} In normal and retinal degeneration chickens, quantitative OCT signals have also been shown to provide a predictable relationship between histology and pathology.\textsuperscript{65}

Imaging of macular diseases with OCT and its correlation with fluorescein angiography and fundus examination has been studied in a series of pathologies, such as full- and partial-thickness macular hole, epiretinal membrane, macular edema, intraretinal exudate, idiopathic central serous chorioretinopathy, and detachments of the pigment epithelium and neurosensory retina.\textsuperscript{66} Macular imaging with OCT has been shown to provide new information concerning posterior pole diseases and in thickness measurements, and is expected to be useful in studying internal layers of the retina.\textsuperscript{67} Quantitative assessment of macular edema with OCT can be used for objectively monitoring retinal thickness with high resolution in patients with macular edema. OCT can be a sensitive diagnostic test for the early detection of macular thickening in patients with diabetic retinopathy.\textsuperscript{68,69}

There is some doubt about the usefulness of OCT in patients with nonexsudative age-related macular disease (AMD). Although drusen, alteration of the retinal pigment epithelium, and secondary retinal changes could be identified, other structures such as basal laminar (linear) deposits could not be seen with this method.\textsuperscript{70} In a study of age-related macular degeneration and choroidal neovascularization (CNV), OCT proved useful in quantitatively evaluating subretinal and intraretinal fluid, assessing possible subfoveal involvement of neovascularization, and in monitoring classic CNV before and after laser photoagulation. OCT was, however, unable to detect CNV beneath serous pigment epithelial detachments.\textsuperscript{71}

OCT has also been used to study optic disk pit maculopathy. OCT confirmed the two-layer structure of optic disk pit maculopathy and that the improvement in central vision after pneumatic displacement coincides with a reattachment of the outer limiting membrane in the macula. Furthermore, the hypothesis that the inner layer separation of the retina, which persists, provides a conduit for the continuous flow of fluid from the pit to the displaced retinal elevation has also been supported.\textsuperscript{72,73}

OCT also provides information useful in surgery. For example, it has provided a structural assessment of the macula that was useful in the preoperative and postoperative evaluation of epiretinal membrane surgery.\textsuperscript{74} OCT has also been used to document fundus changes after Ar laser photocoagulation treatment of retinal branch vein occlusion,\textsuperscript{75} and to evaluate macular thickness changes after cataract surgery.\textsuperscript{76}

As a result of its high depth resolution OCT is well suited to measure retinal layer thicknesses such as the nerve fiber layer (NFL). This layer is of relatively high reflectivity owing to its horizontally aligned components.\textsuperscript{62} NFL thickness can be reproducibly measured using OCT\textsuperscript{77} and has demonstrated a high degree of correlation with the functional status of the optic nerve, as measured by visual field examination.\textsuperscript{78} In a study on focal defects of the NFL, OCT yielded a sensitivity of 65% and a specificity of 81%.\textsuperscript{79} OCT has been used to detect NFL thinning in eyes with ONH drusen and glaucoma, and appears to be a sensitive and early indicator of NFL thinning.\textsuperscript{80,81}

A study of the retinochoroidal structures seen in idiopathic polypoidal choroidal vasculopathy showed that cross-sectional OCT images may increase the understanding of the pathophysiology of this disease.\textsuperscript{82} In vivo imaging of choroidal tumors by OCT has not yet been successfully demonstrated. Choroidal or choriocapillary reflectivity was nonspecifically lower than that of normal choroid but did not yield any additional information about tumor histology. OCT may only provide information about the retinal structure overlying prominent tumors and the extent of adjacent retinal detachment.\textsuperscript{83} Retinal detachment has also been effectively quantified in central serous chorioretinopathy.\textsuperscript{84}

In the anterior segment of the eye, corneal thickness and profile, anterior chamber depth and angle,
5.2 Other Medical Fields and Optical Coherence Tomography Biopsy Imaging

Conventional biopsy and histopathology relies on microscopic inspection of excised tissue specimens. However, excision of a tissue specimen is often contraindicated or impossible. As OCT provides a resolution comparable to conventional histology, but in real time, it has a high potential for use in real-time optical biopsy. OCT does not require excision of tissue with its associated complications, cost, and delay in obtaining a diagnosis. Moreover, large regions may be surveyed for pathology, and conventional biopsy can be reserved only for those regions in which abnormalities are detected by OCT imaging.

OCT biopsy imaging can be used in animal experiments to noninvasively image developing neural morphology and to assess the developing cardiovascular system. Using a 1-mm diameter catheter endoscope, cross-sectional images of the rabbit gastrointestinal and respiratory tracts have been obtained at 10 µm resolution (Figure 19). Images of human in vitro venous, coronary artery, and abdominal aorta morphology have been obtained. The advantage of OCT as compared to intravascular ultrasound is a much better resolution with improved delineation between intimal layer and lipid-rich atherosclerotic plaque.

Intraoperative OCT monitoring has been suggested by a study using a surgical microscope integrated with OCT to perform simultaneous imaging with enface visualization. Cross-sectional images were assembled to produce three-dimensional reconstructions of arterial anastomosis and helped identify sites of luminal obstruction.

Other fields of medical OCT applications are:

- **Dermatology** OCT cross-sections showed different skin layers: stratum corneum, stratum germinativum, stratum papillare, epidermis, papillary ridges, papillary dermis, and sweat gland ducts (Figure 20).

- **Gastroenterology** OCT images have demonstrated clear delineation of the mucosa and submucosa and muscularis in gastrointestinal tissues. Microscopic structures such as crypts, blood vessels, or esophageal glands in the submucosa and lymphatic nodules were observed.

- **Dentistry** OCT has been shown to be able to differentiate between the various types of keratinized and nonkeratinized mucosa with high resolution. OCT can also provide detailed structural information on clinical abnormalities (caries and noncaries lesions) in teeth and provide guidance in dental restorative procedures. A hand-held in vivo OCT device for use in the oral cavity has also been developed. OCT images showed the gingival margin, periodontal sulcus, and the dento–enamel junction. The cemento–enamel junction was discernible in 64% of the images and the alveolar bone presumptively identified for 71% of the images.

- **Urology** In urological tissues, taken postmortem, microstructure was delineated, including the prostatic urethra, prostate, bladder, and ureter, with an axial resolution of 16 ± 1 µm, higher than any clinically available endoscopic intraluminal imaging.
technology. OCT provides noncontact high-resolution imaging of urological tissue architectural morphology, without the need for excisional biopsy.

- **Gynecology** OCT imaging of normal and neoplastic human cervical and uterine tissue showed that the structures of the normal ectocervix and endocervix, including epithelium, basal membrane, and glands, could be clearly identified. Because of its high resolution, OCT has the potential for powerful, minimally invasive assessment of the female reproductive tract. Furthermore, micron-scale two- and three-dimensional images obtained of an in vitro oviduct obtained by OCT suggest that it may possible to identify and surgically treat tubal causes of infertility.

- **Neurology** OCT offers increased resolution in the intraoperative identification of brain tumors and tumor margins. Changes in optical backscatter intensity could be used to identify regions of tumor and to locate tumor margins. A comparison of the optical coherence tomographic images with the histological slides showed that OCT can effectively differentiate normal human cortex from intracortical melanoma.

### 5.3 Future Developments

Recent developments which might lead to important future applications are:

- **ODT** Many diseases are caused by ischemic conditions. Pharmacological intervention and therapy change blood flow. Hence, the quantitative assessment of tissue perfusion is of great importance. Nowadays, ultrasound Doppler techniques are well established in the clinic. Based on OCT principles, ODT offers high spatial resolution. So far, ODT imaging of blood flow dynamics and tissue structures in a vivo chick choioallantoic membrane and rodent mesentery, and throughout a beating *Xenopus laevis* heart and surrounding vasculature have been demonstrated.

- **Spectroscopic OCT** Here the depth scan is performed stepwise. Each depth scan step signal is Fourier transformed. As in Fourier transform spectroscopy, the result yields the optical spectrum of the backscattered light, but in OCT the spectra obtained are depth localized. A prerequisite for reasonable spectroscopic OCT, however, is a broadband light source delivering spatially coherent light. The related technique of absorption sensitive OCT imaging is based on a dual-wavelength OCT system; this technique has already been used for measuring the local concentration of water in an intralipid phantom. Polarization-sensitive OCT is a related technique. It can be used to characterize dentin and enamel, to determine the birefringence and the optical axis in fibrous tissue, and may also find applications in material science for the investigation of polarization properties in opaque media such as ceramics and crystals.

Photodynamic Therapy

Beate Röder
Humboldt-University Berlin, Institute of Physics, Berlin, Germany

Photodynamic therapy (PDT) is an effective treatment of different types of cancer, virus infections, skin diseases and others using photosensitizers (PSs) which are nontoxic in the dark but become phototoxic following activation by low energy light. The PS is applied topically or systemically and should be selectively accumulated in the target tissue. The molecular mechanism of the therapy is the photodynamic effect: following light absorption energy is transferred from the PS to molecular oxygen generating singlet molecular oxygen ($^1O_2$) which causes direct or indirect photodamage of the target tissue.

In clinical therapy with first generation PSs like Photofrin$^\text{®}$ typically fluences of around 100 J cm$^{-2}$ of red light are used. The light doses vary in dependence on the treated disease. Using PSs of second generation with very strong absorption in the red region like the very efficient m-tetrahydroxyphenylchlorin (m-THPC), smaller fluences, typically around 10 J cm$^{-2}$, are required. According to the different optical properties and the efficiency of selective accumulation of PS in the target tissue, the drug doses vary from 1–5 mg (first generation PS) to 0.1 mg (second generation PS) per kilogram body weight.

PDT is a very efficient method for the treatment of minor diseases, blood cancer, inoperable diseases like some types of bladder, brain or lung cancer, and breast carcinoma metastases. The side effects are less than in the case of chemother or radiotherapy. The most common side effect is skin photosensitization. The strength of this effect depends on the PS used and also on the patients’ skin type. Most of the new second generation PSs cause no or only weak skin phototoxicity. The therapeutic radius is limited by the penetration depth of the used light (in the order of some millimeters to centimeters). The method will not be very successful for the treatment of large solid tumors.

1 INTRODUCTION

Today it is generally accepted that PDT in the presence of a PS – in most cases these are tetrapyrroles – activated by red light (Figure 1) is an effective treatment for various types of cancer, skin diseases and virus infections. The most commonly used sensitizer in clinical therapy is a complex mixture of porphyrins, derived from hematoporphyrin, termed hematoporphyrin derivative (HPD). This PS is far from ideal, its tumor selectivity is very poor,
and it has only a weak molar absorption coefficient in the red region of the spectrum where tissue penetration is high. In addition, the skin photosensitization caused by hematoporphyrin may continue up to 30 days as has been known since 1913.\(^1\)

For these reasons in recent years beside the so-called first generation PS new compounds with strong photosensitizing properties, high absorption in the far red and less side effects, the so-called second generation PS were developed. Presently scientific interest is focused on the development of carrier systems that increase the selectivity of PS accumulation in the target tissue. For this photo-physically optimized PS of the second generation are used to design together with units which direct them to biologically well defined places in the cells or on cell surfaces new drugs for PDT – the so-called third generation PS.

### 2 HISTORY

The photosensitizing activity has been known since the beginning of this century.\(^2\) For the first time in 1903 the use of combined dye and illumination for the treatment of skin diseases was proposed.\(^3\) These first reports were followed by broad research activity in the 1940s and 1950s with a lot of interesting results.\(^4,5\) Nevertheless the use of the photodynamic effect was limited to skin diseases at this time.

In the mid-1970s this “soft” noninvasive therapy became of greater interest in medicine because of the very fast development of laser and fiber optics.\(^6,7\) Using these new techniques it was possible now to treat all surfaces in the human body attainable with fiber optics of a diameter of some hundreds of micrometers.

### 3 MOLECULAR MECHANISM OF PHOTODYNAMIC THERAPY

The molecular mechanism of the photodynamic effect has been under investigation for a long time and a first scheme was given by Foote.\(^8\) He postulated two types of photosensitization both occurring in the presence of molecular oxygen. The Type I process includes charge transfer and the Type II pathway energy transfer (EnT) processes. Later a third way of photosensitization the Type III which occurs in the absence of molecular oxygen and includes charge transfer was postulated by Laustriat.\(^9\) Accepting this broad definition of photosensitization also photoinduced electron transfer processes (e.g. photosynthesis) can be treated as photosensitized reactions. The processes relevant for photosensitization occurring after light absorption by the PS molecule are summarized in Figure 2. After absorption of a light quantum the PS is excited directly to the first excited singlet state (S\(_1\)) or passes from a higher excited singlet state (S\(_n\)) to the S\(_1\)-state. In general energy and electron transfer processes can occur from this excited electronic state. Nevertheless the most important step in photosensitization is the process of intersystem crossing (ISC) converting the PS to the long-lived first excited triplet state (T\(_1\)). Because of the special properties of molecular oxygen (see section 3.3) a very efficient EnT from the PS in the T\(_1\)-state may occur resulting in the generation of singlet molecular oxygen (\(^1\)O\(_2\)). From the triplet state of the PS also charge transfer reactions are possible resulting in radical formation.

#### 3.1 Types I, II, and III of Photosensitization

All three pathways of photosensitization start from the first excited triplet state of the PS. In Figure 3 these processes are shown schematically.

#### 3.1.1 Type I

This mechanism occurs in the presence of molecular oxygen. Following electron transfer from the PS to
3 Photodynamic Therapy

3.1 Types of Photosensitization

3.1.1 Type I

The processes of Type I and II photosensitization take place in a system at the same time, which means that they are running in competition. The relative efficiency of both pathways is mainly defined by the physicochemical properties of the system. At normal oxygen concentration and neutral up to physiological pH-value in most cases the Type II mechanism will dominate. Using simple model systems a distinction between the two types of photosensitization can be made on the basis of different photoproducts.

3.1.2 Type II

Figure 3 Types of photosensitization starting from the first excited triplet state of the PS ($3^1$PS) with R – substrate molecules – and O$_2$ – molecular oxygen.

The most important step is the EnT from the PS in its $T_1$-state to molecular oxygen. As a result singlet molecular oxygen ($^1$O$_2$) is produced. During this step the PS is transformed to the ground state ($S_0$) and can absorb another quantum of light. That means – the PS plays the role of a “catalyst”. Using moderate light doses in PDT (which do not cause the photodestruction of the PS) every PS molecule can generate thousands of $^1$O$_2$ molecules. The photosensitized generated $^1$O$_2$ can interact directly with substrate molecules like proteins or lipids. Also the production of oxygen radicals in a high amount is possible which permit additional phototoxic reactions. In other words: Type II mechanism is a very efficient catalytic chain reaction process. It needs only low amounts of PS to generate a strong phototoxic answer of the system.

3.1.3 Type III

This type is similar to the Type I in so far as radicals are also produced but in contrast to Type I photosensitization discussed above the reactions occur in the absence of molecular oxygen and/or at very high local concentrations of the reactants. The excited PS molecule directly interacts with the substrate molecule. Via electron transfer from the first excited singlet or triplet state of the PS to substrate molecules radicals are formed.

3.2 Photophysical Properties of Photosensitizers

From the scheme of the molecular processes of photosensitization discussed above (Figure 2) it can be deduced that potent PSs must possess a high triplet quantum yield and long triplet lifetime to obtain high singlet oxygen quantum yields. Such behavior is known from macrocyclic systems where the ISC is not longer forbidden because of the spin-orbit-coupling. The activation energy of $^1$O$_2$ is 0.98 eV (22.4 kcal mol$^{-1}$), which means that potent PS should have triplet energies higher but near 0.9 eV. In other words compounds with high ISC quantum yield and strong absorption in the red or far red region (650–850 nm) could be effective PSs for both the Type I and Type II mechanisms. In general such compounds would be also effective PSs for Type III processes.

3.3 Singlet Molecular Oxygen

Singlet molecular oxygen plays a key role in PDT. It is the only activated oxygen species which can be generated by electronic excitation via EnT. The special properties and the important role of molecular oxygen results from its extraordinary electronic structure. This molecule has two unpaired electrons in the ground state. For this reason the ground state of molecular oxygen is a triplet state ($T_0$), in contrast to the most common molecules which have a “closed shell” conformation in the ground state ($S_0$). The first excited electronic state of molecular oxygen is
a singlet state (S1 : 1Δg so-called: 1O2). That means 1O2 is generated as a result of a spin-forbidden ISC process. The direct excitation of this state with laser irradiation is possible but has very low quantum yields.\(^{(13)}\)

For the generation of 1O2 only a very small amount of energy (0.98 eV) is needed. The lifetime of 1O2 strongly depends on the environment. In solution it can adopt values between 700 µs in CCl4 and 3 µs in aqueous solution. An overview on singlet oxygen decay times in a very big number of solvents is given in Wilkinson et al.\(^{(14)}\) To excite the second excited singlet state (1Σg\(^+\)) which has a very short lifetime (about 10\(^{-10}\) s in solution), already 1.6 eV is needed. The first excited triplet state (3Σg\(^+\)) is located in the ultraviolet (UV) region. Because of these energetic conditions only the first excited singlet state 1Δg of molecular oxygen (\(^1\)O2) is of interest for biomedical applications.

For estimating the potential photosensitizing efficiency of a given compound the determination of its singlet oxygen quantum yield (Φ\(_\Delta\)) is a useful tool. This value can be obtained from a kinetic analysis of the relevant processes shown in Figure 2. As a result we get Equation (1)

\[
\Phi_\Delta = \frac{k_{ISC}(k_{rad} + k_{IC} + k_{ISC})^{-1}}{(k_{EnT}[O_2])k_{ISC} + k_{rad} + k_{EnT}[O_2])^{-1}S_\Delta}
\]

with the rate constants (k) of the ISC, internal conversion (IC), radiative deactivation (rad), and EnT. [O2] is the concentration of molecular oxygen. The factor S_\Delta takes into account that not all PS in the triplet state are deactivated via EnT to molecular oxygen. For most molecules the value of S_\Delta is much smaller than one but for the tetrapyrroles it approaches nearly one. Simplifying Equation (1) we get Equation (2):

\[
\Phi_\Delta = \Phi_{ISC}\tau_T k_{EnT}[O_2]S_\Delta
\]

From this equation it can be deduced that Φ_\Δ depends not only on the triplet quantum yield (Φ_{ISC}) but also on the triplet lifetime (τ_T) of the PS under the given experimental conditions which are strongly dependent on the oxygen concentration and other environmental factors. Quantum yield and lifetime of the first excited triplet state of molecules are also influenced by the inner heavy atom effect. For this reason in general only a few atoms like zinc and magnesium should be used as central atoms in tetrapyrrolic PS.\(^{(15)}\)

The transition of 1O2 to the ground state is forbidden according to different selection rules. This results in a very low rate constant of the radiative deactivation and the observed lifetime mainly depends on the nonradiative deactivation processes. Depending on the solvent the quantum yields range between 10\(^{-5}\) and 10\(^{-6}\).

---

The production of 1O2 can be measured using indirect (chemical) or direct (chemiluminescence, phosphorescence) methods. Chemical methods are based on the use of monitoring molecules like 1,3-diphenyl-isobenzofuran. From the obtained amount of photoproducts Φ_\Δ can be calculated. These methods are useful only in homogeneous environments.\(^{(16)}\) Mainly dimol reactions are used for the detection of 1O2 via chemiluminescence\(^{(17)}\) (Table 1). Nevertheless the small rate constant of the radiative deactivation is high enough for direct detection of the 1O2-luminescence at 1270 nm. With the Ge-detectors available today steady-state as well as time-resolved detection in homogeneous and microheterogeneous environments is possible.\(^{(18,19)}\) The direct detection of 1O2-luminescence in vivo is impossible with the present experimental technique. The reason is the very short lifetime of 1O2 in organisms caused by very efficient competitive quenching processes. Up to now only computations of the lifetime of 1O2 in cells exist. Moan et al.\(^{(20)}\) proposed a lifetime of 10–40 ns with a corresponding diffusion distance of 10–20 nm, and Meffert et al.\(^{(21)}\) proposed diffusion distances of about 60 nm. For this reason indirect methods for the evidence of 1O2 generation in cells like the measurement of consumed oxygen and the efficiency of phototoxic reactions\(^{(22)}\) or the determination of the triplet lifetime of the PS\(^{(23)}\) at different oxygen concentrations in the tissue are used.

---

### 4 PRINCIPLE OF PHOTODYNAMIC THERAPY

PDT is based on the use of the principle of photosensitization to get as much as possible phototoxicity. The advantages of this therapy are the use of low energy radiation which is not absorbed by biomolecules and water, and the catalytic action of the PS molecules. Strictly speaking PDT is based on the Type II pathway of photosensitization – the photodynamic effect. The principle of PDT is schematically shown in Figure 1. Nevertheless as pointed out before (see section 3) in general three mechanisms...
of photosensitization can be distinguished. The Type I involves the generation of radicals in the presence of oxygen where the PS does not play a catalytic role. The Type III pathway describes the direct chemical reaction between photoexcited PS and the substrate molecules under deaerated conditions, the quantum yield is low and relatively high PS concentrations like in chemotherapy are needed. In other words no photodynamic effect occurs in these two cases of photosensitization. For this reason therapeutic treatments based on Type I and Type III mechanisms will be mentioned only briefly.

4.1 Photochemotherapy (Type I/III of Photosensitization)

In vivo it is not easy to discriminate between the Type I and Type II mechanism because they are competitive processes. In the “classical” photochemotherapy the photodynamic effect is not used and the phototoxic effects are therefore mainly due to Type I processes. Typical Type I agents are psoralens like the 8-methoxypsoralen used in the PUVA-therapy of psoriasis. Nevertheless they are also known to generate $^1\text{O}_2$ \(^{(24)}\) Photosensitizing processes via Type III mechanism with remarkable quantum yields are known only from experiments carried out in solvents.\(^{(9)}\) Classical photoinduced electron transfer processes are not regarded here.

4.2 Photodynamic Treatment (Type II Photosensitization)

As was mentioned before the limiting factors of the efficiency for this treatment are the photophysical properties of the PS, the oxygen concentration during the treatment and the localization of the PS molecules in the tissue. In this section we will focus on the mutual dependence of the first two factors.

PS used in PDT absorb light in the red or far red region. For this reason it is important to know the optical properties (absorption and scattering) of normal and tumor tissue in this region. Wilson et al.\(^{(25)}\) gave an overview on direct and indirect methods for the measurement of optical properties of tissue. Profio et al.\(^{(26)}\) investigated the energy fluence rates of light in dependence of absorption and anisotropic scattering for different geometries. Svaasand et al.\(^{(27)}\) carried out detailed studies on the penetration depth of light with different wavelengths for normal tissue and human intracranial tumors. All these authors found penetration depths of some millimeters in the red region which was about 2–3 times larger than in the green/blue region. Using PSs of the second or third generation which absorb at wavelengths of about 680 nm to 780 nm the penetration depth may rise in dependence on the tissue up to centimeters.

In recent years the possibility of simultaneous two-photon activation of PS is under discussion. The advantage of this method is the use of near-infrared radiation from YAG\(^{28,29}\) or Ti:Sa-lasers\(^{30}\) which once more allow a deeper penetration of the light. A review on the present knowledge and broad discussion of the advantages and problems of simultaneous two-photon stimulation is given in Fisher et al.\(^{(30)}\)

Together with the photoactivation of the PS the question of the role of tumor oxygenation during photodynamic treatment becomes important. Foster et al.\(^{(31)}\) investigated the oxygen consumption and diffusion effects in PDT and developed a mathematical model of the Type II mechanism. They found that during PDT carried out at incident light intensities of 50 mW cm\(^{-2}\) molecular oxygen can be consumed at rates of 6–9 µM s\(^{-1}\). Thus, during photoradiation the actual oxygen concentration may strongly decrease. It can become low enough to minimize or preclude $^1\text{O}_2$-mediated processes and as a result photodestruction of the PS may occur. Their analysis further suggests that the use of fractionated light (30 s exposure followed by 30 s dark periods) can overcome partially the oxygen depletion. In this regime a significantly longer delay in tumor growth was produced when compared to the regime of continuous illumination of the same total light dose.

The common photodynamic treatment is a continuous one-photon activation process. The PS doses differ depending on the absorption coefficient of the PS at the excitation wavelength. For PS of the first generation it is about 1–5 mg kg\(^{-1}\) body weight. The light doses used for these PSs at 610–620 nm are about 50–100 mW cm\(^{-2}\).

Summarizing these facts we can conclude that the common treatment is not carried out under optimized conditions. Efficient photodynamic treatment should be done using fractionated simultaneous two-photon activation of PS.

4.3 Photoactivity from Higher Excited States of Photosensitizers

As was shown in Figure 2 the PS can be excited to higher electronic singlet states ($S_n$) using UV-light or sequential two-photon absorption (SPA). Proposing relatively long-lived $S_n$-states (some picoseconds) and low ISC-quantum yields it should be possible to generate radicals different from those generated via the Type I pathway.\(^{(32,33)}\) First experiments with SPA on HPD\(^{34}\) and protoporphyrin IX (PP)-dimethylester\(^{35}\) showed that in this case not only Type I and II but also oxygen-independent reactions occur. Nevertheless until now SPA has not been used in clinical application.
5 PHOTOSENSITIZERS

Different classes of substances have been investigated for their photodynamic activity. It is well known that such substances like erythrosine or methylene blue which are used as dyes in cytology and dental medicine have high singlet oxygen quantum yields and may cause photodynamic effects.\(^{(36,37)}\) Also some common toxins (adriamycin, daunomycin) used in the chemotherapy of cancer are able to generate \(^{1}\text{O}_2\) under irradiation.\(^{(38)}\)

A special problem is the therapy of brain tumors because of the blood–brain barrier. Beside tetrapyrroles also chalcogenaprylium dyes are under investigation.\(^{(39,40)}\) Also dyes with absorption in the green region of the spectrum like Merocyanine 540 are evaluated for their photosensitizing properties. Such dyes become important for the treatment of single cells, e.g. leukemic cells.\(^{(41)}\)

Nevertheless the most important chemical class of potent PSs are tetrapyrroles. The large conjugated \(\pi\)-electron system guarantees high triplet quantum yields. Changes of the central atom, or of the substitution at different binding sites as well as the possibility to extend the macrocyclic system allow a wide range of modifications to fine-tune the electronic properties of these substances. Thus specific PS for the treatment of different diseases can be designed. An actual overview on the chemistry of potent porphyrin-based PS is given by Sternberg et al.\(^{(42)}\)

For this reason the next section will focus on PS from the class of tetrapyrroles.

5.1 Exogenous: First, Second, and Third Generation of Photosensitizers

Because of the broad variety of tetrapyrroles a large number of possible PS were prepared during the last twenty years. An overview on the chemistry, and some aspects of photodynamic activity is given by Bonnett.\(^{(43)}\) For this reason only selected important PSs will be discussed in this paper. The structural formula of some selected PSs belonging to the different groups of tetrapyrroles are shown in Figure 4. Some important photophysical parameters of some representative compounds are summarized in Table 2.

5.1.1 First Generation Photosensitizers

Porphyrins (Figure 4) were the initial PS in PDT. The history started with hematoporphyrin. Later HPD, a mixture of different porphyrins\(^{(57)}\) was under detailed investigation. It emerged that the photoactive compounds are mainly dimers or higher aggregates. Such a mixture with a high content of the photoactive compounds is commercially available under the name Photofrin\(^{(6)}\) I and II (see sections 1 and 8). Photofrin\(^{(6)}\) was the first PS in clinical practice. Other porphyrins were also studied and it was found that coproporphyrin – Type III\(^{(38)}\) – and protoporphyrin\(^{(39)}\) have good photosensitizing properties. Berenbaum et al.\(^{(60)}\) investigated the photodynamic activity of tetraphenylporphyrins (TPP) in vitro and Sacchini et al.\(^{(61)}\) carried out a preclinical study using sulfonated TPP for the treatment of neoplastic tissue in topical application. The disadvantages of all these porphyrins are the weak absorption in the red region of the spectrum (\(\lambda < 5000\) mol\(^{-1}\) cm\(^{-1}\) at 630 nm) and serious side effects like skin photosensitization for 4 to 6 weeks.\(^{(62)}\)

5.1.2 Second Generation Photosensitizers

It was the intention to overcome these disadvantages that led to the development of second generation PS. These PS were to combine strong absorption in the red or near infrared region together with high singlet oxygen quantum yields and weak side effects. The first group of tetrapyrroles investigated under these aspects were the benzoporphyrins. These compounds have a strong absorption around 692 nm\(^{(63)}\) and their phototoxicity is 10–70 times higher\(^{(64)}\) than that of HPD.

A very promising group of PS are systems that are based on reduced porphyrins, i.e. tetrapyrroles possessing a chlorin or bacteriochlorin skeleton. The lack of one or two double bonds in the tetrapyrrole macrocycle leads to a pronounced shift in the absorption spectra, generating systems with increased absorption in the red region, which is obviously very attractive for PDT.

Phorbides are a group of tetrapyrroles derived from the naturally occurring chlorophyll and have strong absorptions around 670 nm. A very efficient representative of this group is phorphorbid A. Its photodynamic activity was shown in vitro\(^{(65)}\) and in vivo\(^{(66,67)}\). A broad variety of phorbides and pyropheophorbides was studied for their photodynamic activity during the last few years. A review of these activities is given in Röder.\(^{(68)}\)

Under similar conditions also the photodynamic activity of derivatives of bacteriochlorophyll and bacteriopheophorbide was investigated.\(^{(69,70)}\) In comparison to chlorophyll derivatives these compounds have a strong red-shifted absorption at around 740 nm. This makes them very promising compounds for the treatment of melanoma tumors.\(^{(71,72)}\)

Two other compounds derived from natural chlorin systems that interest has focused on are chlorin \(e_6\) and mono-L-aspartylchlorin (Npe6). For both substances very good photoactivity in vitro and in vivo\(^{(73,74)}\) was shown. Nowadays the in vivo activity of the artificial chlorin \(m\)-THPC is studied intensely.\(^{(75)}\) First results of clinical trials...
showed that this compound is the most effective PS at this time (see section 8).

A lot of different compounds of the class of purpurins were synthesized and characterized. A few of them (e.g. SnNT2H2, SnET2, SnET2H2) show very good PDT response in vivo. The data of these compounds are summarized by Garbo.\(^76\)

Another possibility to increase the strength of absorption is the extension of the macrocyclic ring system. As a result porphycenes,\(^77\) texaphyrins\(^78\) and sapphyrins\(^79\) were synthesized and investigated. From this group the Lutetium texaphyrin, a water soluble PS, is the most promising compound. This molecule contains a 22\(\pi\)-electron macrocycle that causes a strong absorption at 740 nm. The complexation with a metal causes an increased ISC quantum yield together with very weak fluorescence quantum yields. First results of in vivo investigations are given by Kostenich et al.\(^80\)

Because of the very strong absorption in the far red also the use of tetra-azaporphyrins – PCs and NPCs – was investigated. The photodynamic activity of different PCs and NPCs was demonstrated with a broad variety of compounds. Detailed studies were carried out using different Zn-PC,\(^81\) or ClAl-PC.\(^82,83\) Recently results are reported which suggest that using a silicon PC PS may avoid side effects like skin photosensitization.\(^84\) The use of NPC is more problematic because of the absorption at wavelengths around 800 nm. This may cause a back

To date much fundamental research on the photosensitizing properties and photodynamic activity of tetraarylporphyrins has been carried out using a large variety of compounds, but only a few compounds have reached the stage of clinical trials.$^{(74,88,89)}$ These compounds together with their advantages and disadvantages, the selling company, and treated diseases are summarized in Table 3 (section 8).

5.1.3 Third Generation Photosensitizers

After twenty years of clinical PDT a variety of very efficient PS exist with excellent photophysical properties. The unsolved problem today is the “right” location of PS in the cell or at the cell surface. To solve this problem different strategies are employed. One possibility is the use of drugs specifically designed for
Table 3  PS of the first and second generation in clinical trials. (Data taken from several sources[127–136])

(continued overleaf)
treatment of one disease. In this case the PS itself has a binding site with strong affinity to a special locus of the target cell type or is coupled with some molecule preferably accumulated by this cell type. The following two examples should explain this idea. To enhance the photodynamic activity of chlorin $e_6$ by its delivery to specific, sensitive intracellular compartments of target cells Akhlynina et al.\(^{90}\) prepared a bovine serum albumin–insulin–chlorin $e_6$ complex that was bound specifically to the insulin receptors of a human hepatoma cell line. They found an enhancement of photodynamic activity of about two orders of magnitude. Water soluble serine conjugates of chlorophyll and bacteriochlorophyll were successfully used in the treatment of mice bearing melanoma tumors.\(^{72}\)

Another possibility is the use of modular carrier systems (see section 6.3). Both strategies have the intention to get a selective accumulation and to increase at the same time the concentration of PS in the target tissue. Such PS having biological active sites for selective accumulation are developing and named third generation PS.

### 5.2 Endogenous: 5-Aminolevulinic Acid Therapy

The principle of ALA therapy differs from the other photodynamic treatments because a precursor of the active PS is applied. ALA is the natural precursor of endogenous porphyrins. The exogenously applied ALA stimulates the intracellular production of PP and the endogenously produced PS is accumulated in malignant cells.\(^{91,92}\) In 1990 the ALA therapy was proposed by Kennedy et al.\(^{93}\) as a new phototherapeutic modality. It was found that ALA penetrates through human skin and topical application of ALA has been used for the treatment of different skin diseases in human: actinic keratoses, basal cell carcinoma,\(^{94,95}\) and psoriasis.\(^{96}\) (see also Table 3, section 8). The disadvantages of this therapy are side effects like skin photosensitization and pain. Using animal models also the treatment of brain tumors,\(^{97}\) and of viral infections\(^{98}\) are reported. It has also been shown that intravenously injected ALA preferentially accumulates in melanoma.\(^{99}\)

### 6 DRUG DELIVERY SYSTEMS

One of the crucial problems in any therapy is the selective action of the drugs used. All the discussed PSs of first and second generation do not exhibit active selective accumulation. Concentration gradients of PS accumulation between normal and tumor tissue are mainly caused by metabolic differences. As a result time-shifted accumulation peaks of PS in different tissues are found. These differences may become high (up to a relationship of 1:50), so that they can be used in photodynamic treatment. Anyway such relations are not good enough for experienced clinical use. Moreover the nonspecific accumulation of PS is the reason for common PDT side effects. Another problem concerns the positioning of the PS molecules at the therapeutically important sites of the cells. To increase the selectivity and to avoid side effects different PS delivery systems were created based on different PS and tissue properties: immunotargeting, high molecular weight PS complexes, and lipophilic properties of PS. Nevertheless using the delivery systems described in the following sections (6.1 and 6.2) the problems could be solved only partly.

#### 6.1 Carrier Molecules

The use of carrier molecules is directed on a selective and highly concentrated accumulation of PS molecules in the cells or at the cell surface. Different strategies have been developed which use the properties of malignant cells or of a special cell type.

**Immunotargeting** Covalent bonding of PS molecules to antibodies.\(^{100}\) It has been demonstrated that the complexation of chlorin\(^{100}\) with a monoclonal antibody does not influence the $^{1}O_{2}$ quantum yield. Later it was shown that PS–antibody complexes lose their immune activity if more than eight PS molecules are bound to one antibody.\(^{101}\) Consequently only a defined quantity of PS given by the binding sites of antibodies on the cell surface can be delivered to the cells.
**High Molecular Weight Photosensitizer Complexes**

PSs with polyvinyl chains are used by different authors to deliver chlorins\(^{(101,102)}\) or NPC\(^{(87,103)}\). Krinick et al.\(^{(102,104)}\) proposed a delivery system containing water soluble polymer coupled via a degradable spacer to the PS (meso-chlorin \(e_6\)).

### 6.2 Carrier Systems

The common carrier systems – micelles and liposomes – use the lipophilic properties of PS. A broad number of different micelle forming detergents were investigated but mainly Tween 80 and Cremophor\(^{®} \) EL were used for PS delivery.\(^{(105,106)}\) In comparative studies of these carrier systems different pharmacokinetics for a NPC were found.\(^{(107)}\) Woodburn et al.\(^{(108)}\) reported an influence of the delivery systems on the physical properties of plasma lipoproteins, resulting in the formation of a lipoprotein degradation product.

It is known that serum lipoproteins play an important role in the in vivo transport of PSs. Mosley et al.\(^{(109)}\) proposed the use of low-density lipoproteins (LDLs) as carrier systems for selective delivery of PS to tumor cells. Kesseler\(^{(110)}\) showed that LDL–PS complexes where the PS is associated with the lipid moiety of LDL are largely accumulated via a receptor-mediated endocytotic process. Further investigations showed the existence of a correlation between the extent of sensitizer – LDL association and the efficiency of selective PS accumulation in tumor tissue. The extent of LDL association of PS strongly depends on the hydrophobicity of the PS. A detailed discussion on the role of LDL in the delivery of PS is given by Jori et al.\(^{(111)}\). The delivery of Zn-PC to LDL using liposomes was investigated by Reddi et al.\(^{(112)}\). They found that the extent of ZnPC accumulation depends on the content of cholesterol in the liposomes. The use of liposomes as PS delivery system is well accepted and used for sensitizers of the first and second generation: HPD\(^{(113)}\), BPD-MA,\(^{(114)}\) pheophorbide,\(^{(115)}\) PC,\(^{(112)}\) NPC,\(^{(86)}\).

All of these systems have the disadvantage that relatively large carrier systems have to be used to deliver one or only a small number of PS molecules to the target tissue. For this reason nowadays more efficient delivery systems which are able to carry a large number of PS molecules are under investigation. Moreover the selective accumulation of PS using the described delivery systems was not as high as expected.

### 6.3 Modular Carrier Systems

Nowadays the use of modular carrier systems and polyphasic tumor targeting (PTT) are proposed to get high concentrated and selective – biologically defined – accumulation of PS. The intention of this concept is the attachment of PS molecules to one addressee – and one multiplying unit – the so-called third generation PS.

The sense of these systems is the spatial separation of PS from the localizing part of the carrier system and the attachment of a large number of PS molecules to one carrier unit (see Figure 5).

The idea to use modular carrier systems in the so-called PTT was suggested first by Moser.\(^{(116)}\) He proposed a modular carrier system containing monoclonal antibodies as the addresssee and an avidin–biotin complex (AB-C) as the multiplying unit. Every AB-C has four binding sites, three of them are saturated with PS molecules the fourth with the next AB-C. First in vitro experiments showed that the concept in general works very well.\(^{(89)}\) But problems could arise using this modular carrier system containing several AB-C in vivo (since avidin is a large protein with a molecular weight of 70000).

To avoid the immune problems arising from application of high molecular weight proteins the possibility of using other classes of molecules has been proved. In this context dendrimers were under investigation. Third generation starburst dendrimers were covalently linked on an average of twelve PS molecules and their photophysical and photobiological properties were studied. First in vitro results suggest that dendrimers could become very efficient multiplying units. An additional advantage of this system consists in the light-induced abstraction of PS molecules from the dendrimer. That is, a large number of PS can be transferred directly to target tissue by one carrier unit which has no immune activity.

---

**Figure 5 Schematic diagram of a modular carrier system loaded with PS molecules.**

---

7 COMMON LIGHT SOURCES

The light doses used in clinical therapy depend on the photophysical properties of the PS and the tissue properties. Typically in the treatment with Photofrin\(^{®} \) red
light with fluences between 50 and 100 J cm\(^{-2}\) are used. (At higher fluences hyperthermic effects may occur.) For the treatment of a tumor area of 10 cm\(^2\) a power of approximately 0.3–0.6 W at the surface is needed.

According to the stronger absorption of second generation PS the fluences decrease to about 10 J cm\(^{-2}\) in the case of m-THPC. Also the wavelength of the used light is shifted to 670–740 nm, that means to lower energies.

In general dosimetry of light irradiated tissue is a rather complex problem. Various different applicators were developed to irradiate tissue surfaces of different geometry homogeneously (e.g. scattering spheres or fiber tips). However one of the crucial problems in PDT is the action radius of the photodynamic effect. This value strongly depends on the penetration depth of laser light, which may vary for different tissues. A practical approach to measure light fluence rates in vivo is given by Steiner et al.\(^{(118)}\)

### 7.1 Lasers and Light-emitting Diodes

The common light sources in PDT are dye lasers pumped by conventional lasers, like Ar-, Cu-, or Nd:YAG (frequency doubled) lasers. Dye lasers typically deliver useful light in a spectral range of about 60 nm. This is a serious limiting factor in clinical practice where different PS for the treatment of different diseases should be used.

Nowadays the development of more cost-effective sources like light-emitting diodes (LED) could give the possibility to use optimum light sources for different treatments. The development of a novel LED type based on Al:Ga:arsenide allows the peak wavelength to be varied between 630 nm and 940 nm depending on the relative content of aluminum and gallium. Schmidt et al.\(^{(119)}\) constructed a LED probe for in vivo studies containing 144 of such LED chips. The bandwidth of emitted light was 25 nm with the emission peak at 677 nm. The LED probe was placed in a conventional laser balloon adapter which was adjusted to deliver 363 J cm\(^{-2}\) for every treatment.

### 7.2 Lamps

Also the successful use of lamps, especially in the treatment of skin diseases is reported. Recent advantages in lamp miniaturization and of optical filter coatings led to the development of some special light sources for PDT. De Jode et al.\(^{(120)}\) used a 5 W metal halide lamp delivering a 40 nm band in the red and 0.45 W at the end of a light guide. Whitehurst et al.\(^{(121)}\) developed an equipment with a short arc lamp delivering a 30 nm band between 300 nm and 1100 nm with an output power of 1 W and 0.5 W via a light guide. First in vitro experiments suggest that the efficiency of this light source is similar to a cw Ar-pumped dye laser.

### 7.3 Pulsed Lasers

Beside cw-light sources an increasing interest in the use of short-pulsed lasers exists (see section 4.1). These lasers could be used in simultaneous two-step absorption of light. Because of the longer wavelengths of the used light deeper tissue penetration is suggested.\(^{(28–30,122)}\)

Solid-state lasers (Ti:Sa; Nd:YAG; Nd:YLF) with second-, third- or fourth-harmonic generating and optical parametric oscillators could become important light sources in PDT because of their variable emission between the deep UV and the near infrared region. These laser systems are still developing to higher power. Otherwise the development of strong absorbing PS results in smaller PDT light doses. For these reasons the importance of these laser systems in PDT will probably increase in the future.

### 8 CLINICAL APPLICATIONS

The modern history of clinical application of the photodynamic effect began in 1966 when Lipson et al.\(^{(123)}\) for the first time treated one patient with HPD. The first systematic PDT study in human was reported by Dougherty et al.\(^{(124)}\) in 1978. Today Photofrin\(^{®}\) is approved worldwide and used in the treatment of different tumors and diseases (see Table 3). Overviews on clinical experiences with Photofrin\(^{®}\) in recent years are given by Evensen,\(^{(125)}\) Jocham\(^{(126)}\) and Dougherty et al.\(^{(127)}\) As was pointed out (see section 5) Photofrin\(^{®}\) is far from an ideal PS. For this reason second generation PSs were developed and some of them are in clinical trials (Table 3).

#### 8.1 Photodynamic Therapy of Skin Diseases and Cancer

PDT studies using new PS are at first mainly focused on the treatment of psoriasis and of cutaneous and subcutaneous tumors because of the possible topical administration of PS. Because of this, a great variety of results exists in this field but only some examples illustrating the typical behavior of these PS will be briefly discussed.

Collins et al.\(^{(137)}\) reported on the treatment of 22 patients with plaque psoriasis using topical administered ALA and broadband visible radiation (10–40 mW cm\(^{-2}\)). They observed a clearance of psoriasis in some patients after a single treatment.

Szeimis et al.\(^{(94)}\) treated actinic keratoses of ten patients with 36 lesions topically with ALA and red light (150 W cm\(^{-2}\)). They observed a complete remission in 71% of actinic keratoses located on the head.
Taber et al.(74) used the new PS Npe6 for the treatment of patients with different superficial malignancies, including recurrent adenocarcinoma of the breast, basal cell carcinoma and squamous cell carcinoma (single i.v. injection of 0.5–3.5 mg kg\(^{-1}\) Npe6; incubation time: 4 h; light: 25–100 J cm\(^{-2}\) at 664 nm). They observed an increased tumor response at higher PS doses (2.5 mg kg\(^{-1}\)) and no side effects, excluding a temporary skin photosensitivity.

Razum et al.\(^{(138)}\) reported about a 95–100% response of basal cell carcinoma 12 weeks after the treatment with 1.2 mg kg\(^{-1}\) SnET2 (incubation time: 1 day; light: 200 J cm\(^{-2}\) at 660 or 664 nm). BPD-MA\(^{(139)}\) and Lu-Tex\(^{(140)}\) were also successfully applied for the treatment of various types of skin diseases. Using Lu-Tex which is strongly absorbing light around 730 nm a complete response of subcutaneous melanoma tumors was found.

Clinical trials in different phases for the treatment of other tumors (see Table 3) using second generation PS are still running. Detailed and statistical reliable data are not available yet.

### 8.2 Photodynamic Therapy of Other Diseases

Beside the treatment of skin diseases and various types of cancer the photodynamic effect could be used also in the treatment of other diseases:

- Viral infections (Herpes, Papilloma, HIV)
- Macula degeneration
- Bacterial infections in caries
- Arteriosclerosis
- Rheumatoid arthritis and other clinical indications.

Already preliminary studies with encouraging results have been done. **Antiviral activity:** Photodynamic inactivation of viruses has been discussed as a useful tool for blood banking\(^{(141)}\) the successful treatment of Herpes simplex\(^{(97,142)}\) as well as the antiviral efficiency of PSs\(^{(97,143)}\) and immunonjugates\(^{(144)}\) against HIV have been shown. **Macula degeneration:** Preliminary results obtained with BPD-MA\(^{(145)}\) have been reported. **Antibacterial activity:** Photosensitizing activity of PC on Escherichia coli\(^{(146)}\) of protoporphyrin on Candida cells\(^{(147)}\) and of a deuteroporphyrin-hemin mixture on gram positive bacteria\(^{(148)}\) are reported. Also photoactive antibacterial immunonjugates containing Sn-chlorin \(\varepsilon_6\) were synthesized\(^{(149)}\). The photodynamic effect was also used to treat Streptococcus infections in caries.\(^{(150)}\) **Arteriosclerosis:** Preliminary investigations using animal models are reported.\(^{(151,152)}\)

### 9 COMPARISON AND COMBINATION WITH OTHER METHODS

Compared with other tumor therapies PDT has the advantage of rather selective action. Serious side effects are not known. The observed long time skin phototoxicity of the first generation PS like Photofrin\(^®\) could be overcome with the optimized second generation PS. The effective radius of PDT is determined by the penetration depth of the excitation light. That means PDT will be used mainly for the treatment of small or at the surface of some organ located diseases. This limiting value gives at the same time the advantages that even inoperable tumors can be treated successfully (e.g. bladder, lung). Compared with chemotherapy PDT is acting more selective at lower drug doses and without the well known complications. As it is shown in the following sections the therapeutic effect can be enhanced treating tumors with a combination of PDT with conventional therapies.

#### 9.1 Chemotherapy

As already discussed molecular oxygen is needed to induce photodynamic effects. During PDT hypoxia in the treated tissue may arise due to the enhanced generation of \(\text{O}_2\) under illumination. One possibility to avoid this situation is the fractionated illumination with light. Another possibility to achieve therapeutic effects under these conditions is the combination of PDT with chemotherapy using hypoxic toxins. Preliminary studies in tumor mice showed an enhanced therapeutic effect when both therapies were combined.\(^{(153)}\) Baas et al.\(^{(154)}\) reported on the combined treatment of four patients with mammary skin metastases. For this treatment the PS Photofrin\(^®\) was combined with the hypoxic toxin mitomycin C. They found an enhanced effect even at reduced sensitizer and light doses.

#### 9.2 Radiotherapy

It is well known that X-ray-irradiation may cause an increase of blood flow in some tumors for some days. Consequently reoxygenation of tumor cells occurs\(^{(155)}\) and the cell sensitivity to further irradiation increases. The time needed for reoxygenation depends on the X-ray-dose and tumor type. Therefore different authors investigated the effect of combined PDT and radiotherapy. Graschew et al.\(^{(156)}\) combined Photofrin\(^®\) and local X-ray-irradiation for their studies on the mouse sarcoma tumor model. They found a significant enhancement of the therapeutic effect. The best result was obtained when the PDT irradiation followed 24 h after the radiotherapy. At this time tumor reoxygenation was maximized. Surprisingly they also observed some enhancement when PDT
preceded radiotherapy. Such effect was also described by Kostron et al.\textsuperscript{(157)} They suggest a radiosensitizing effect of HPD.

### 9.3 Hyperthermia

It is also known that the efficiency of radiotherapy can be enhanced by hyperthermia. For this reason the effect of combined PDT and local hyperthermia in animal tumor models was studied by different authors. A comparative study on three different tumor models showed that the therapeutic effect was enhanced for simultaneous application of both therapies. For such treatment of the sarcoma 180 in mice a synergistic effect was observed.\textsuperscript{(153)}

### 9.4 Cryotherapy

Morton et al.\textsuperscript{(158)} carried out a study on patients with Bowen’s disease to compare the efficacy of cryotherapy and PDT. ALA was used as a topically administered PS. They found a significantly higher probability for the clearance of lesions after one PDT treatment compared with cryotherapy. Following the treatment with cryotherapy side effects like ulceration, infection and also recurrent diseases were observed. Following PDT such complications did not occur.

### 9.5 Immunotherapy

The mechanism of tumor destruction caused by PDT treatment includes a variety of pathways leading to the death of tumor cells.\textsuperscript{(159)} One of these events is the inflammation of the treated tissue associated with massive invasion of activated myeloid cells. Beside the tumor cell destruction an immune development process starts resulting in the generation of tumor-specific immune memory cells. In difference to the local character of PDT treatment this process can have a systemic character inducing an immune reaction of the organism. Thus, the specific cells generated by PDT can be used in further treatments to eradicate lesions (e.g. metastases) of the same cancer. Different regimes of immunotherapy were proofed in animal tumor models. It was found that PDT can be successfully combined with different immunotherapy regimes. A detailed discussion on the prospects of combined PDT-immunotherapy is given by Korbelik.\textsuperscript{(159)}

### 10 OUTLOOK

The experienced use of PDT in the near future will depend mainly on the development of efficient selective PSs of the third generation which cause no side effects and on the development of low-cost light sources like LED. More and more new areas of PDT application become important. Beside the “classical” use in the treatment of tumors and various skin diseases the soft noninvasive PDT is also still under improvement for its use in the therapy of rheumatoid arthritis, arteriosclerosis, age-related macular degeneration processes, and of viral and bacterial infections. A better understanding of the processes leading to the destruction of tumor cells will result in optimized therapeutic regimes. This may include fractionated or SPA irradiation of the treated areas and also the combination with other established tumor therapies.

### ABBREVIATIONS AND ACRONYMYS

- AB-C: Avidin–Biotin Complex
- ALA: 5-Aminolevulinic Acid
- BPD-MA: Benzoporphyrin Derivative–Monoacid Ring A
- EnT: Energy Transfer
- HPD: Hematoporphyrin Derivative
- IC: Internal Conversion
- ISC: Intersystem Crossing
- LDL: Low-density Lipoprotein
- LED: Light-emitting Diodes
- Lu-Tex: Lutetium–Texaphyrin
- m-THPC: m-Tetrahydroxyphenylchlorin
- NPC: Naphthalocyanine
- PC: Phthalocyanine
- PDT: Photodynamic Therapy
- PP: Protoporphyrin IX
- PS: Photosensitizer
- PTT: Polyphasic Tumor Targeting
- SPA: Sequential Two-photon Absorption
- TPP: Tetraphenylporphyrins
- UV: Ultraviolet

PHOTODYNAMIC THERAPY

117. B. Röder, St. Hackbarth, G. Wöhlecke, ‘Verfahren zur Nutzung von Dendrimeren als Multiplikatoren zur Verabreichung von Photosensibilisatoren’, Patentantrag, Registration Nr. 199 36 997.6 (2 August, 1999), Germany.

Two-dimensional vibrational correlation spectroscopy offers a new opportunity for analyzing vibrational spectra. In the 2-D approach, spectral peaks are spread over the second dimension, thereby simplifying the visualization of complex spectra consisting of many overlapped bands, and enhancing spectral resolution. Correlation peaks appearing in the synchronous and asynchronous maps represent in-phase and out-of-phase variation tendencies of corresponding band intensities, respectively. 2-D correlation spectroscopy is very useful in unraveling infrared (IR), near-infrared (NIR), and Raman spectra of biological molecules and biomedical materials. For example, it has a powerful deconvolution ability for highly overlapped amide I, amide II, and amide III bands of proteins, enabling these bands to be assigned to various secondary structures. 2-D NIR correlation spectroscopy provides new insights into the hydration of proteins, and can also be used to investigate the order of perturbation-dependent structural changes.

1 INTRODUCTION

In 2-D correlation spectroscopy, a spectrum is obtained as a function of two independent spectral variables, such as wavenumbers. Introduction of the second spectral dimension provides a new opportunity for analyzing spectra. 2-D correlation spectroscopy was initially evolved as an analytical data treatment method for sinusoidally varying dynamic IR signals detected in studies of molecular interactions. In 1993 it was extended to generalized 2-D correlation spectroscopy, which uses a more generally applicable, yet reasonably simple, mathematical formalism. The application of the newly proposed 2-D correlation spectroscopy to various other types of spectroscopy, such as Raman and NIR spectroscopy, is straightforward.

1.1 History of Two-dimensional Correlation Spectroscopy

The basic working concept for 2-D vibrational correlation spectroscopy was developed much later than more well-established 2-D correlation techniques pioneered in the field of nuclear magnetic resonance (NMR) spectroscopy. Today it may seem surprising that this powerful yet simple idea, of obtaining a spectrum as a function of two independent spectral axes, was not applied to vibrational spectroscopy until a decade or so ago. In fact, several vibrational spectroscopists, inspired by the prolific expansion of successful 2-D NMR activities, had previously expressed some interest in such adaptations of multidimensional correlation schemes to their field. However, many believed that the fundamental differences in the timescales dealt with by different spectroscopic techniques were an insurmountable obstacle in applying the 2-D idea developed for NMR to common vibrational spectroscopy. It is well known that the characteristic time span of molecular vibrational processes (picosecond range) is many orders of magnitude shorter than the typical spin relaxation times (microsecond range or even longer) encountered in NMR. In NMR, the double Fourier transformation of a set of time domain data collected under multiple-pulse excitations generates 2-D spectra. Direct adaptation of such a procedure, based on pulsed excitations, to conventional vibrational spectroscopy is rather difficult. Ordinary commercial IR spectrometers, for example, cannot adequately provide the rapid excitation and detection of vibrational relaxation responses needed to carry out such measurements. Thus, the specific experimental procedure developed for 2-D NMR had to be fundamentally modified before being applied to IR or Raman spectroscopy.
Early attempts at 2-D vibrational spectroscopy were still heavily influenced by the basic approach set by NMR, where only time-dependent changes in spectral signals are utilized for 2-D correlation. Thus, the first generation of 2-D vibrational correlation spectra were obtained from IR experiments based on the detection of various relaxation processes, which are much slower than vibrational relaxations but are closely associated with molecular-scale phenomena. These slow relaxation processes can be studied with a conventional IR spectrometer using a simple time-resolved technique. Dynamic 2-D IR rheo-optics experiments, based on the IR dichroic measurement of orientational relaxation processes of molecular segments of various plastic films subjected to a small amplitude oscillatory deformation, gained considerable popularity, especially among polymer scientists. In addition to such mechanically stimulated experiments, similar 2-D IR works based on time-dependent IR signals induced by sinusoidally varying electrical or photoacoustic perturbations have also been tried.

In 1993 the concept of 2-D vibrational correlation spectroscopy was significantly expanded to include much more general forms of spectroscopic applications. The mathematical procedure to yield 2-D correlation spectra from sinusoidally varying time-dependent spectral signals was modified to handle arbitrary time dependences which were much more complex than a simple sinusoidal wave. The type of spectral signals analyzed by the newly proposed 2-D correlation method became virtually limitless, covering IR, Raman, X-ray, ultraviolet (UV), fluorescence, and many more. Most importantly, it was finally recognized that this powerful 2-D correlation technique could be adopted for the analysis of spectral signals which change as functions not only of time but also of any other reasonable physical variables (such as temperature, concentration, pH, pressure, or any combination of these). Such a generalized correlation idea truly revolutionized the scope of potential applications for 2-D spectroscopy, especially in the field of IR and Raman spectroscopy.

1.2 Characteristics of Two-dimensional Correlation Spectroscopy

Figure 1 shows a basic scheme for constructing generalized 2-D correlation spectra from perturbation-induced dynamic fluctuations of spectroscopic signals. In the generalized 2-D correlation method, there are many different types of external perturbations which could be used to stimulate a system of interest. When an external perturbation is applied to the system, various chemical constituents of the system are selectively excited. The excitation and subsequent relaxation processes towards the equilibrium are monitored with various kinds of electromagnetic probes. In order to generate generalized 2-D correlation spectra, a set of dynamic spectra must be calculated first (see section 2.1). Then, two kinds of correlation spectra, known as synchronous and asynchronous spectra, are constructed from the dynamic spectra.

The new generalized 2-D correlation method can handle signals that fluctuate as an arbitrary function of time. Thus, a large number of time-dependent spectral variations associated with transient phenomena can be systematically analyzed. Furthermore, it has become apparent that the same 2-D correlation concept can be equally well applied to static systems of interest using any physical variables other than time, such as temperature, pressure, or even concentration. This has opened up the possibility of introducing the versatility of 2-D correlation analysis to much wider ranges of applications, including electrochemistry, photochemistry, and reaction kinetics.

The major advantages of generalized 2-D correlation spectroscopy may be summarized as follows.

1. Spectral resolution is enhanced by spreading spectral peaks over the second dimension. In other words, spectral information not readily accessible from one-dimensional (1-D) spectra is available.
2. More detailed investigations of various inter- and intramolecular interactions are possible through selective correlation of peaks.
3. The specific order of the spectral intensity changes can be probed.
4. Band assignments can be made based upon correlations between various bands.
5. Correlations between bands in two different spectroscopic techniques, such as Raman and IR spectroscopies, can be studied.
2 THEORY

2.1 Mathematical Treatment

The detailed mathematical treatment for generalized 2-D correlation spectroscopy has been described by Noda[2,21] elsewhere. Here, we describe the basic concept briefly. Let us consider a time-dependent fluctuation of spectral intensity \( y(v, t) \) observed for a period of time between \(-T/2\) and \(T/2\). The variable \( v \) can be any appropriate spectral variable, e.g., IR wavenumber, Raman shift, or even X-ray diffraction angle. In order to generate generalized 2-D correlation spectra from perturbation-induced dynamic fluctuations of spectroscopic signals, the dynamic spectrum must be calculated first. It is defined in Equation (1) as

\[
\tilde{y}(v, t) = \begin{cases} 
  y(v, t) - \bar{y}(v) & \text{for } -T/2 \leq t \leq T/2 \\
  0 & \text{otherwise}
\end{cases}
\]  

(1)

where \( \bar{y}(v) \) is the reference spectrum. Although the selection of the reference spectrum is somewhat arbitrary, \( \bar{y}(v) \) is usually set to be the static or time-averaged spectrum, defined as shown in Equation (2).

\[
\bar{y}(v) = \frac{1}{T} \int_{-T/2}^{T/2} y(v, t) \, dt
\]  

(2)

For many practical systems the reference spectrum may also be set to zero.

For the next step, it is necessary to Fourier transform the dynamic spectra measured in the frequency domain. The dynamic spectral intensity fluctuations \( \tilde{y}(v_1, t) \) observed at some spectral variable \( v_1 \) are Fourier transformed to \( Y_1(w) \) as shown in Equation (3)

\[
Y_1(w) = \int_{-\infty}^{\infty} \tilde{y}(v_1, t) e^{-iwt} \, dt
\]  

(3)

where \( Y_1^{\text{Re}}(w) \) and \( Y_1^{\text{Im}}(w) \) are the real and imaginary components of the complex Fourier transform of \( \tilde{y}(v_1, t) \). The Fourier frequency \( w \) represents the individual frequency component of the time-dependent variation of \( \tilde{y}(v_1, t) \). Similarly, \( Y_2(w) \), the conjugate of the Fourier transform of dynamic spectral intensity \( \tilde{y}(v_2, t) \) at spectral variable \( v_2 \), is given by Equation (4).

\[
Y_2(w) = \int_{-\infty}^{\infty} \tilde{y}(v_2, t) e^{iwt} \, dt
\]  

(4)

\[
= Y_2^{\text{Re}}(w) - iY_2^{\text{Im}}(w)
\]

Now, one can define the complex 2-D correlation intensity between \( \tilde{y}(v_1, t) \) and \( \tilde{y}(v_2, t) \) by Equation 5.

\[
\Phi(v_1, v_2) + i\Psi(v_1, v_2) = \frac{1}{\pi T} \int_{-T/2}^{T/2} Y_1(w)Y_2^*(w) \, dw
\]  

(5)

The real and imaginary components of the complex 2-D correlation intensities, \( \Phi(v_1, v_2) \) and \( \Psi(v_1, v_2) \), are the generalized synchronous and asynchronous correlation spectra of the dynamic spectral intensity variations.[2,21]

The synchronous spectrum represents the overall similarity of the time-dependent behavior of spectral intensity variations measured at two separate wavenumbers, while the asynchronous spectrum represents the overall differences in dynamic spectra.

The synchronous and asynchronous spectra are explained in more detail later. It is important to note that the time used in the above 2-D correlation analysis can actually be regarded as a general variable which could be replaced by any other reasonable physical variable, such as temperature, pressure, or distance.[22]

This extension of the correlation concept, from a simple time-series analysis of transient spectral fluctuations to a more general scheme of spectral analysis, made 2-D correlation spectroscopy a much more versatile and universally applicable tool. While the formal definition of the 2-D correlation intensities is mathematically rigorous, it is rather cumbersome and time-consuming to calculate the actual correlation intensities based upon the above definition. Therefore, Noda[21] developed a new algorithm which allows 2-D correlation spectra to be calculated much more simply. The method does not rely on Fourier transformation but is based on the Hilbert transform, offering an easier and more efficient way for calculating the 2-D correlation. In this case the 2-D correlation spectra can be calculated according to Equations (6) and (7)

\[
\Phi(v_1, v_2) = \frac{1}{T} \int_{-T/2}^{T/2} \tilde{y}(v_1, t)\tilde{y}(v_2, t) \, dt
\]  

(6)

\[
\Psi(v_1, v_2) = \frac{1}{T} \int_{-T/2}^{T/2} \tilde{y}(v_1, t)\tilde{z}(v_2, t) \, dt
\]  

(7)

where the orthogonal spectrum \( \tilde{z}(v_2, t) \) is a time-domain Hilbert transform of \( \tilde{y}(v_2, t) \).

A more detailed mathematical treatment for calculating synchronous and asynchronous 2-D correlation spectra has been described.[21]

2.2 Properties of Generalized Two-dimensional Correlation Spectra

Figure 2(a) and (b) illustrates a schematic example of synchronous and asynchronous 2-D correlation spectra.
The synchronous spectrum is symmetric with respect to a diagonal line corresponding to spectral coordinates $v_1 = v_2$. The intensities of peaks located at diagonally opposing positions correspond to the autocorrelation functions of spectral intensity variations. These diagonal peaks are therefore referred to as autopeaks. In the spectrum shown in Figure 2(a), there are four autopeaks located at the spectral coordinates A, B, C, and D. The intensities of the autopeaks represent the overall extent of dynamic fluctuations of spectral signals. Cross-peaks located at the off-diagonal positions of a synchronous 2-D spectrum represent the simultaneous changes in signal intensities at two different wavenumbers. In the example spectrum, bands A and C are synchronously correlated, as are bands B and D. If the sign of the cross-peak is positive, the intensities at corresponding spectral variables increase (or decrease) together. On the other hand, the sign becomes negative if one of the spectral intensities is increasing while the other is decreasing.

The asynchronous 2-D correlation spectrum shown in Figure 2(b), which consists exclusively of off-diagonal cross-peaks, provides information complementary to the synchronous spectrum. It represents sequential changes in spectral intensities distinguished by different temperature (time, concentration, etc.) events measured at $v_1$ and $v_2$. Asynchronous cross-peaks develop only if the intensities of two dynamic spectral intensities vary out of phase with each other for some Fourier-frequency components of signal fluctuations. This feature is especially useful in differentiating between overlapped bands arising from different spectral origins or moieties. The sign of an asynchronous cross-peak can be either negative (as indicated by the shaded areas) or positive. It becomes positive if the intensity change at $v_1$ occurs predominantly before $v_2$ (i.e. in the earlier part of the sequentially arranged spectral data set). This rule, however, is reversed if $\Phi(v_1, v_2) < 0$. The example spectrum in Figure 2(b) indicates that the intensity changes at bands A and C occur before the changes at B and D (i.e. in the later part of the data set).

3 APPLICATION TO BIOMEDICAL SCIENCES

2-D correlation spectroscopy is a powerful tool in the analysis of complicated spectra of biological molecules and biomedical materials. For example, it enables the highly overlapped amide I, II, and III bands of proteins to be resolved into component bands ascribed to various secondary structures. It is also possible to investigate the correlations between amide I, II, and III
bands. Moreover, correlation between IR bands due to fundamental amide modes and NIR bands due to their combinations may be studied.

The first examples of the application of 2-D correlation spectroscopy to biomedical sciences were 2-D IR studies on the stratum corneum of human skin\textsuperscript{[11]} on keratin films from human hair.\textsuperscript{[20]} Recently, generalized 2-D correlation IR spectroscopy has been extensively employed to investigate the secondary structure of proteins. Nabet and Pézolet\textsuperscript{[12]} demonstrated the potential of 2-D IR correlation spectroscopy in exploring the conformation of proteins using hydrogen–deuterium (H–D) exchange. Sefara and Richardson\textsuperscript{[13]} investigated the structure of β-lactoglobulin using both 2-D IR and 2-D NIR correlation spectroscopy. Wang et al.\textsuperscript{[14]} reported 2-D NIR correlation analysis of concentration-dependent spectral changes in albumin solutions at various temperatures. New insight has been gained into the hydration and unfolding processes of secondary structures of ovalbumin by studying temperature-dependent correlation patterns in 2-D synchronous and asynchronous spectra. The 2-D correlation spectra for this study were constructed from concentration-perturbed NIR spectra at different temperatures. In addition to the standard 2-D IR and 2-D NIR analysis, 2-D infrared/near-infrared (IR/NIR) heterospectral correlation analyses of the thermal unfolding of ribonuclease A (RNase A) were carried out by Schultz et al.\textsuperscript{[15]} The 2-D correlation analyses suggested that different structure elements in RNase A respond slightly differently to a temperature increase.

Gadaleta et al.\textsuperscript{[8]} applied 2-D IR correlation spectroscopy to synthetic and biological apatites. They investigated the hydroxyapatite (HA) maturation, complex spectral contours undergoing changes as crystals ripen.

In section 3.1 the applications of 2-D correlation spectroscopy are described, by dividing them into two areas: applications to protein research, and other biomedical applications.

### 3.1 Applications to Protein Research

#### 3.1.1 Two-dimensional Infrared Correlation

**Spectroscopy Study on the Secondary Structure of Proteins using Hydrogen–Deuterium Exchange**

Fourier transform infrared (FTIR) spectroscopy has emerged as a valuable tool for qualitative and quantitative estimation of the secondary structure of proteins. Although many attempts have been made to assign the components of the amide I band to secondary structures such as α-helices and β-sheets, it is still a matter of controversy. 2-D IR correlation spectroscopy enhances the spectral resolution of the amide I and II regions and makes it possible to assign some of the amide I and II bands to given conformations.

Nabet and Pézolet\textsuperscript{[12]} reported a 2-D FTIR correlation spectroscopy study of the secondary structure of myoglobin. They used H–D exchange of the amide protons as an external perturbation to generate the 2-D synchronous and asynchronous spectra. Because the amide protons associated with each conformation are not exchanged simultaneously, the different conformational contributions of the amide bands can be separated. Analysis of the synchronous and asynchronous maps of myoglobin shows that this method is very useful for unraveling the different components of the poorly resolved amide I, II, and III bands of proteins.

Microgram quantities of thin myoglobin films were deposited on attenuated total reflection (ATR) crystals, and H–D exchange was induced by hydrating the films with a flow of nitrogen containing D\textsubscript{2}O vapor. In general, there are two kinds of amide groups involved in the deuteration kinetics: some amide groups that are readily accessible are exchanged rapidly at the beginning of the deuteration process, whereas those in structures that are less accessible to the solvent show slower exchange kinetics. Thus, to separate the fast kinetics from the slower ones more efficiently, different sampling times were used.

Figure 3(a) shows the synchronous 2-D IR correlation spectra of myoglobin calculated from the first 10 spectra recorded during the H–D exchange process, while Figure 3(b) shows the asynchronous spectra. Figure 4 depicts the corresponding spectra calculated from 10 spectra obtained approximately 1h after the beginning of the H–D exchange process.\textsuperscript{[12]} The amide I region of the synchronous correlation map for the rapidly exchanging protons (Figure 3a) shows three correlation peaks at 1675, 1640, and 1615 cm\textsuperscript{-1}. These amide I components are respectively assigned to the β-turns, random coil, and intermolecular β-sheets often found in aggregated proteins. Therefore, it seems that the amide groups associated with these three conformations are exchanged first during the deuteration process. The strongest peak in the synchronous map is observed in the amide II region at 1530 cm\textsuperscript{-1}, while in the amide II’ region two major peaks can be identified at 1440 and 1350 cm\textsuperscript{-1}.

The asynchronous map of myoglobin for the rapidly exchanging protons develops two cross-peaks in the amide I region, at 1675–1640 cm\textsuperscript{-1} and at 1640–1615 cm\textsuperscript{-1}, confirming that the three peaks at 1675, 1640, and 1615 cm\textsuperscript{-1} appearing in the synchronous map are due to three different conformations.

In the synchronous map for the slowly exchanging protons, one autopack is observed at 1655 cm\textsuperscript{-1}, a frequency that is generally assigned to the amide I mode of the α-helix conformation. Thus, it is very likely that the amide protons of the α-helix conformation are exchanged more slowly than those associated with intermolecular β-sheets, random coil, and β-turns.\textsuperscript{[12]} The other intense
peaks, observed at 1545 and 1345 cm\(^{-1}\), may be assigned to the amide II and amide II' modes of the \(\alpha\)-helices of myoglobin, respectively.

The synchronous spectrum for the slowly exchanging system (Figure 4a) also has a weak component at 1625 cm\(^{-1}\). This component could be due to the \(\beta\)-sheet conformation. Since the random coil and the \(\beta\)-turn structures do not develop the amide I components in the synchronous map calculated for the longer time domain, the H–D exchange rate for the \(\beta\)-sheet structure seems
to be slower than those for the random coil and β-turn structures.

3.1.2 Two-dimensional Near-infrared Spectroscopy
Study of Heat Denaturation of Ovalbumin in Aqueous Solutions

Wang et al.\textsuperscript{(14)} studied heat denaturation of ovalbumin in aqueous solutions using 2-D NIR correlation spectroscopy. NIR spectroscopy is useful in studying hydration and hydrogen bonds in proteins. In NIR spectra of aqueous protein solutions, a number of bands due to overtones and combination modes arising from water and amide groups of proteins can be observed. They are more sensitive to changes in the hydration and hydrogen bonds than IR bands ascribed to water and the amide groups. NIR spectroscopy has one serious problem, in that a number of bands overlap each other to make spectral analysis more difficult.

The purpose of the study by Wang et al.\textsuperscript{(14)} was to investigate the potential of generalized 2-D NIR correlation spectroscopy in exploring subtle differences in NIR spectral responses concerned with structural changes in proteins. Temperature-dependent NIR spectra were measured for ovalbumin solutions over a temperature range from 45 to 80 °C, which covers the whole heat denaturation process. A series of dynamic NIR spectra modulated by the concentration at representative temperatures, such as 45, 76, and 80 °C, were used to construct 2-D synchronous and asynchronous correlation spectra.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5.png}
\caption{NIR spectra in the 4900–4550 cm\textsuperscript{-1} region for ovalbumin solutions with concentrations of 0, 2, 5, and 8 wt%: (a) at 45 °C; (b) at 80 °C. (Reprinted with permission from Wang et al.\textsuperscript{(14)} Copyright 1998 American Chemical Society.)}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure6.png}
\caption{Second derivative NIR spectra in the 4900–4550 cm\textsuperscript{-1} region for ovalbumin solutions with concentrations of 0, 2, 5, and 8 wt%: (a) at 45 °C; (b) at 80 °C. (Reprinted with permission from Wang et al.\textsuperscript{(14)} Copyright 1998 American Chemical Society.)}
\end{figure}
Figure 5(a) and (b) shows NIR spectra in the 4900–4550 cm\(^{-1}\) region for ovalbumin solutions with concentrations of 0, 2, 5, and 8 wt% measured at 45 and 80 °C, respectively, where the protein is in the natively folded and partially unfolded states.\(^{(14)}\) It is not possible to identify any band in the spectra except for a tail of the strong absorption band of water near 5200 cm\(^{-1}\). The corresponding second derivatives of the spectra in Figure 5(a) and (b) are presented in Figure 6(a) and (b), respectively.\(^{(14)}\) Note that the calculation of the second derivative makes some bands visible. Two bands at 4850 and 4600 cm\(^{-1}\) in Figure 6(a) and (b) are assigned to combinations of free NH stretching of amide II (amide A/II) and intramolecular hydrogen-bonded NH stretching of amide II (amide B/II) of ovalbumin, respectively.

Figure 7 shows synchronous and asynchronous 2-D correlation maps constructed from the concentration-perturbed NIR spectra of ovalbumin solutions at 45 and 80 °C.\(^{(14)}\) The synchronous spectra (Figure 7a and c) exhibit two strong autopeaks at 4850 and 4800 cm\(^{-1}\) at 45 °C. The two peaks probably correspond to the combination band of the amide A/II and to the second overtone of OH bending (3\(v_2\)) of water, respectively. The appearance of the autopeaks means that the intensities of these two bands vary most significantly as the concentration in the folded state increases. In addition, positive cross-peaks (4850 vs 4800 cm\(^{-1}\)) are seen in the synchronous spectra, indicating that their band intensities increase in phase (simultaneously).

Asymmetric cross-peaks at (4850, 4600) cm\(^{-1}\) and (4800, 4600) cm\(^{-1}\) dominate the asynchronous map in
Figure 7(b). The asynchronous spectrum reveals that the amide B/II at 4600 cm\(^{-1}\) shows an out-of-phase variation with the amide A/II and 3\(\nu\)\(_2\) bands. According to the rule proposed by Noda\(^{(12)}\) for determining the sequential relationships between different bands, the negative peaks at (4850–4600) cm\(^{-1}\) and (4800, 4600) cm\(^{-1}\) in Figure 7(b) indicate that the intensity of the amide B/II band changes at a lower concentration than do those of the amide A/II and 3\(\nu\)\(_2\) bands.

A strong autopeak at 4610 cm\(^{-1}\) in the synchronous spectrum at 80 °C (Figure 7c) means that the intensity of the amide B/II band varies most significantly in the spectra of the unfolded state. The two autopeaks at 4850 and 4800 cm\(^{-1}\) in the synchronous spectrum at 45 °C (Figure 7a) become weak in the corresponding spectrum at 80 °C (Figure 7c). Instead, new positive cross-peaks appear at (4860, 4610) cm\(^{-1}\) in the synchronous map at 80 °C, indicating that the intensities of the amide A/II and the amide B/II bands vary in phase. The simultaneous intensity change between the amide A/II and the 3\(\nu\)\(_2\) in the folded state vanishes completely. Moreover, the 3\(\nu\)\(_2\) band changes out of phase with the amide A/II and amide B/II, as verified by the corresponding asynchronous spectrum (Figure 7d). The asynchronous spectrum of the denatured unfolded state at 80 °C (Figure 7d) develops two pairs of new cross-peaks at (4860, 4780) cm\(^{-1}\) and (4780, 4610) cm\(^{-1}\). These peaks confirm the out-of-phase intensity variation of the 3\(\nu\)\(_2\) band with amide A/II and amide B/II.

Another important finding in the 2-D spectra is that the amide A/II and amide B/II bands shift upward by about 10 cm\(^{-1}\) while the 3\(\nu\)\(_2\) band shifts downward by some 20 cm\(^{-1}\) as the temperature increases from 45 to 80 °C. Wang et al.\(^{(14)}\) ascribed these shifts to the thermally-induced unfolding of the secondary structure of ovalbumin.

A series of the 2-D correlation maps were calculated over a temperature range from 45 to 80 °C at intervals of 2 °C to investigate how the correlation plots vary with temperature during the heat denaturation process.\(^{(14)}\) The 2-D correlation patterns below 65 °C and above 71 °C are very similar to those obtained at 45 and 80 °C, respectively. They do change markedly in a very narrow temperature range between 67 and 69 °C. It was concluded that during the hydration process ovalbumin is almost unchanged below 65 °C, then undergoes a sudden change from the native to the denatured state in the 67–69 °C region, and again changes little above 71 °C. The unfolding of secondary structures starts at about 69 °C and continues progressively until 80 °C.\(^{(14)}\) Therefore, the change due to hydration takes place earlier than the unfolding process. It is likely that the hydration change in the critical temperature region between 67 and 69 °C brings about the unfolding process at 69–80 °C.

The 2-D NIR correlation spectroscopy study of ovalbumin also provided new insight into thermally-induced conformation changes in the secondary structure and changes in the hydrogen bonds of the amide groups.\(^{(14)}\)

3.1.3 Conformational Changes of Ribonuclease A upon Thermal Unfolding Studied by Two-dimensional Infrared, Near-infrared, and Infrared/Near-infrared Correlation Spectroscopy

Schultz et al.\(^{(15)}\) reported 2-D IR, 2-D NIR, and 2-D IR/NIR correlation spectroscopy studies on conformational changes of RNase A upon thermal unfolding. The IR and NIR spectra of RNase A were measured in a sodium cacodylate buffer made up in either H\(_2\)O or D\(_2\)O over a temperature range from 20 to 80 °C. Generalized 2-D correlation analysis was then applied to the spectra. One of the purposes of their study was to demonstrate the potential of NIR spectroscopy in monitoring structural changes of proteins in aqueous solutions. To establish correlations between NIR and IR bands, 2-D IR/NIR heterospectral correlation analysis was carried out. These 2-D correlation studies showed that the terminal unfolding of RNase A is not a completely cooperative process; rather it begins with some changes in the β-sheet structure, followed by the loss of α-helical structures, and then ends with the unfolding of the remaining β-sheets.\(^{(15)}\)

Figure 8(a) and (b) shows original IR and NIR spectra of RNase A in H\(_2\)O buffer at 20 °C.\(^{(15)}\) Spectra of the buffer solution (100 mmol sodium cacodylate, pH 2.1) in the corresponding regions are also shown. Figure 8(c) presents IR and NIR spectra of RNase A after subtraction of the buffer.\(^{(15)}\) Subtraction of the buffer spectrum from that of the dissolved protein reveals a number of characteristic protein bands. The IR region is characterized by amide I (1643 cm\(^{-1}\)) and II (1546 cm\(^{-1}\)) bands while the NIR region is dominated by overtones and combination bands involving C–H, N–H, and O–H stretching vibrations. Schultz et al.\(^{(15)}\) proposed the following band assignments based upon previous NIR studies of model compounds: 6616 and 6360 cm\(^{-1}\), the first NH/OH stretching overtones; 5910 and 5767 cm\(^{-1}\), the first overtones of CH\(_2\) stretching; 5060 cm\(^{-1}\), a combination mode involving OH groups; 4866 and 4600 cm\(^{-1}\), combination modes of NH groups; 4368 and 4050 cm\(^{-1}\), combinations involving CH\(_2\) stretching modes.

Figure 9 illustrates IR spectra in the amide I and amide II regions and NIR spectra in the combination band region of RNase A in H\(_2\)O buffer measured at 20, 40, 50, and 80 °C.\(^{(15)}\) The IR spectrum at 20 °C shows a strong amide I band at 1641 cm\(^{-1}\) and a shoulder at 1688 cm\(^{-1}\). These bands indicate the presence of antiparallel β-strands in the native protein. There are major spectral changes between 35 and 50 °C, showing marked structural
changes during unfolding of the protein. Figure 9(a)
shows temperature-dependent intensity changes of the
β-structure “marker” band at 1641 cm$^{-1}$. The intensity
of the band changes mainly between 35 and 50°C. The
spectra measured above 70°C show a broad, featureless
amide I band contour. This contour is typical of a
predominantly irregular protein structure.

The most pronounced spectral changes in the NIR
spectra are observed in the 4900–4860 cm$^{-1}$ region where
a strong combination mode of amide A and amide II due
to peptide groups is expected to appear.$^{15}$ This band
is located at 4867 cm$^{-1}$ at 20°C. As the temperature is
increased, this band loses intensity, becomes broader, and
shifts to higher wavenumbers. The plot of its frequency
versus temperature (Figure 9b) reveals that the frequency
shift of the combination band has the same temperature
dependence as the intensity change in the amide I band.

Figure 10 illustrates (a) synchronous and (b) asyn-
chronous 2-D correlation spectra, generated from IR
spectra of RNase A in H$_2$O buffer measured at various
temperatures (20–70°C).$^{15}$ For the 2-D correlation anal-
yses, the IR and NIR spectra were transformed into
Fourier self-deconvoluted spectra. The synchronous spec-
trum shows autpeaks in the amide I and II regions.
at 1688, 1661, 1652, 1641, 1547, and 1517 cm\(^{-1}\). These autopeaks identify changes that occur in the secondary structure of the protein marked \(\alpha\) for \(\alpha\)-helix and \(\beta\) for \(\beta\)-sheet.

The asynchronous 2-D correlation spectrum enables differences in the stability of different secondary structure elements to be detected. It is not easy to detect such differences by conventional analysis of changes in the 1-D IR spectra of proteins. A close inspection of the asynchronous spectrum of RNase A in Figure 10(b) reveals that the unfolding of the protein does not occur in a single step.\(^{155}\) Asynchronous cross-peaks at (1637, 1644) cm\(^{-1}\) suggest that there are two kinds of \(\beta\)-sheet structures in RNase A characterized by two low-frequency spectral features whose response to a change in temperature is slightly different. It was found that the component at 1637 cm\(^{-1}\) responds earlier during the protein unfolding process than the one at 1644 cm\(^{-1}\). Probably, the slight difference in the frequency is ascribed to slightly different strengths of hydrogen bonding of the C=O groups.

The three \(\alpha\)-helices of RNase A develop only very weak asynchronous cross-peaks (not visible in Figure 10b), indicating that the \(\alpha\)-helices undergo an almost simultaneous unfolding process. One of the bands due to the \(\alpha\)-helices (1656 cm\(^{-1}\)) shows a correlation cross-peak to the two bands of the \(\beta\)-sheet in the asynchronous spectrum, suggesting that the unfolding process of RNase A follows a sequence of three spectroscopic events involving the following bands: 1637/1692 cm\(^{-1}\) (step 1) \(\rightarrow\) 1656 cm\(^{-1}\) (step 2) \(\rightarrow\) 1644 cm\(^{-1}\) (step 3). This sequence means that the first step in the unfolding process is the partial unfolding of the stronger parts of the \(\beta\)-sheet, followed by the unfolding of the \(\alpha\)-helices and then by the unfolding of the weaker parts of the \(\beta\)-sheet.
Figure 10 (a) Synchronous and (b) asynchronous 2-D IR correlation spectra of RNase A in H$_2$O buffer, pH 2.1, at 11 discrete temperatures between 20 and 70 °C. The correlation spectra are represented as intensity maps with a set of 1-D Fourier self-deconvoluted spectra shown outside the maps. (C.P. Schultz, H. Fabian, H.H. Mantsch, *Biospectroscopy*, Copyright © 1998 Wiley-Liss, Inc. Reprinted by permission of Wiley-VCH, Inc., a division of John Wiley & Sons, Inc.)

Figure 11 shows (a) synchronous and (b) asynchronous 2-D IR/NIR spectra generated from the IR and NIR spectra of RNase A measured at 11 temperatures. The 2-D correlation between the two spectral regions allows vibrations of a similar nature to be detected and band assignments in the NIR region to be made based upon established assignments in the IR region. In Figure 11 the positive cross-peaks between the bands in the amide I region and the N−H combination (amide A + amide II) band at 4867 cm$^{-1}$ are notable. They indicate that the amide C=O groups (IR) are highly correlated with the amide N−H groups (NIR). An interesting point in the asynchronous spectrum is that five IR bands at 1675, 1641, 1548, 1525, and 1515 cm$^{-1}$ have an out-of-phase correlation with most NIR bands. For example, the band at 1640 cm$^{-1}$ due to the amide I mode of the β-sheet with slightly weaker hydrogen bonds and the 4865 or 4617 cm$^{-1}$ bands share positive or negative asynchronous cross-peaks. These observations led Schultz et al. to the conclusion that some structure elements in RNase A respond earlier and others respond later to an increase in temperature than the β-sheet structure. The overall conclusion reached by them was that the 2-D correlation analysis of IR and NIR spectra of proteins shows considerable promise of gaining more detailed structural insights into the secondary structure changes.
3.2 Other Biomedical Applications

3.2.1 Human Skin Stratum Corneum

The 2-D IR analysis of protein was first attempted for the dynamic rheo-optical study of proteinaceous components of a human skin stratum corneum specimen. The small sample of human skin was mounted over an IR-transparent thin but robust fluorocarbon (Teflon) substrate film. This composite sample was then acoustically stimulated with a small-amplitude strain at a frequency of 80 Hz to induce time-dependent reorientation of various submolecular constituents. The resulting dynamic IR dichroism spectra of the sample were then analyzed by the 2-D correlation method. Figure 12 shows the amide I and II regions of the 2-D IR spectra for the proteinaceous component of stratum corneum.

The synchronous 2-D spectrum of human skin shown in Figure 12(a) clearly indicates the existence of temporal correlations between certain components of IR bands belonging to the amide I and II modes of vibrations (e.g. 1635 and 1530 cm\(^{-1}\) bands). The highly overlapped composite nature of the amide peaks is clearly demonstrated by the asynchronous spectrum shown in Figure 12(b), which shows the decoupling of the amide I peak into several independent bands. For example, the asynchronous cross-peaks at 1416 and 1635 cm\(^{-1}\) indicate the existence of separate component bands at these wavenumbers. It is interesting to note that while the dipole-transition moments for the different component bands of the amide I peak are reorienting independently of each other, some are coupled with the reorientation of certain amide II component bands.

The synchronously correlated IR band pairs in the human stratum corneum probably originate from common local conformations of polypeptide chains. Thus, it can be speculated that the \(\beta_1\) helix component of the amide I band, for example, will couple with the \(\beta_1\) helix component of the amide II band. Similar arguments may hold for other conformations. By systematically developing 2-D spectra of model polypeptides with known conformations, it may become possible to identify well resolved 2-D vibrational fingerprints of protein conformations. 2-D IR spectroscopy alone obviously will not provide a complete answer to the fundamental questions of vibrational spectroscopy for a very complex biological sample. The technique, however, is a powerful analytical tool which should augment other spectroscopic studies to provide submolecular-level understanding of the system.

3.2.2 Human Hair Keratin

Rheo-optical dynamic 2-D IR spectroscopy is used to study the microstructure of human hair keratin films by carrying out 2-D correlation analysis to time-dependent spectral intensity fluctuations under a small-amplitude oscillatory strain. The mechanical properties of human hair are very sensitive to changes in environmental conditions. For example, simple climatic changes in temperature and relative humidity (RH) can have a dramatic effect on hair set. Cosmetic treatments for hair such as shampooing, conditioning, and permanent waving are also known to affect the mechanical properties of hair fibers. However, surprisingly little is known about the fundamental mechanisms by which these physical changes occur.
2-D IR spectra of keratin films are sensitive to molecular-level changes induced by temperature, RH, and the addition of active ingredients in hair treatments. 2-D IR spectra also provide an attractive spectral resolution enhancement of the naturally broad and highly overlapped amide I and II absorbance bands. The net result is an improved molecular-level understanding of the mechanical properties of human hair and identification of factors affecting the properties of these proteins. Thus, 2-D IR spectroscopy is selected to study the molecular-level origins of the properties of human hair under mechanical perturbations and systematic environmental changes.

A model hair specimen suitable for rheo-optical study was prepared as follows. Clean blended European blonde hair (National Hair, New York) was solubilized by first pulverizing it, and then breaking the disulfide bonds using 8 M urea and 50 mM dithiothreitol. After filtering, the keratin sulfhydryls were alkylated to form S-carboxymethyl keratin (SCMK). The SCMK was dialyzed and thin films were cast from a 10 mg mL\(^{-1}\) 50/50 water/isopropanol solution onto an IR-transparent polyhalocarbon substrate. Finished samples typically measured 4 × 2 cm with a thickness of 25–100 µm (not including the substrate). A 23-Hz dynamic strain with an amplitude of 50 µm was applied to the sample during the measurement. The jaws holding the sample were located in an environmental control chamber. This chamber allowed temperature control to within 0.5 °C and was modified to allow humidity control to within 2% RH. Keratin films were analyzed at temperatures from 30 to 60 °C and at various levels up to about 90% RH. All IR spectra were collected at a nominal spectral resolution of 8 cm\(^{-1}\).

Figure 13(a) shows the asynchronous 2-D IR correlation spectrum of thin keratin (SCMK) films cast from solubilized hair in the amide I region at ambient temperature and humidity. Cross-peaks represent individual submolecular components reorienting at different rates in response to the externally applied perturbation. A clear resolution enhancement of this naturally broad IR absorbance band is achieved. The IR bands resolved by 2-D correlation analysis can be readily assigned to specific conformations, like α-helices (1661 and 1649 cm\(^{-1}\)), β-like extended chains and turns (1679, 1669, 1645, 1641, and 1620 cm\(^{-1}\)), as well as disordered structures (1656 cm\(^{-1}\)). Obviously, such high-resolution mid-IR spectra of condensed-state specimens are not usually available using conventional (1-D) IR methods.

Figure 13(b) shows the corresponding synchronous 2-D IR spectrum of the same system. The synchronous spectrum in the amide I region is dominated by peak clusters of a distinct four leaf clover like pattern, consisting of two autopeaks with two adjacent negative cross-peaks, which is characteristic of α-helical responses.

This amide I region of the 2-D IR spectrum of the keratin changes markedly as a function of temperature. The changes observed correlate well with differential scanning calorimetry (DSC) data of actual hair, showing an irreversible thermal transition near 45 °C. The α-helical four leaf clover feature near 1650 cm\(^{-1}\) in the synchronous spectra remains relatively unchanged as a function of temperature, suggesting that other components such as random or β-like structures are responsible for the differences seen. The effects of high RH and treatment with naphthalene sulfonic acid (NSA) on hair keratin films have been examined by 2-D IR spectroscopy. We found a significant change in dynamic IR signal intensity for bands characteristic of α-helical responses at high RH and after NSA treatment.

The 2-D correlation study suggested new assignments for a band at 1145 cm\(^{-1}\). This band, which had been previously attributed to \(\text{HPO}_4^{2-}\)-containing apatites, has now been assigned to \(\text{PO}_4^{3-}\) vibrations in an apatitic/stoichiometric environment of poorly crystalline HA.

Figure 16(a) and (b) presents the synchronous and asynchronous 2-D IR correlation spectra, respectively, for a series of IR microscopy spectra obtained from the transitional region of calcified turkey leg tendon. Five autopeaks are observed at 1147, 1126, 1075, 1039, and 1019 cm\(^{-1}\). The peaks at 1126, 1039, and 1019 cm\(^{-1}\) correspond to vibrational modes of \(\text{PO}_4^{3-}\) in a nonstoichiometric/acid phosphate environment of poorly crystalline HA, whereas the peak at 1075 cm\(^{-1}\) represents a mode due to \(\text{PO}_4^{3-}\) in an apatitic/stoichiometric environment of poorly crystalline HA. The mineral from the turkey tendon shows a 2-D pattern very similar to the synthetic HA prepared at variable pH. Gadaleta et al. deduced from this comparison of the 2-D IR spectra of the synthetic and biological apatites that the
As demonstrated in these examples, 2-D correlation vibrational spectroscopy has broad applicability in biomedical areas. There may be two directions for future applications. One direction is concerned with applications to basic science, for example 2-D correlation spectroscopy studies of biological macromolecules such as proteins, enzymes, and nucleic acids. Another direction aims at spatial variation of HA maturation of mineral along the tendon matches the temporal variation of HA formed at variable pH.

This study provided new insight into the subtle changes accompanying the maturation of synthetic and biological apatites, as investigated with IR spectroscopy.
more practical applications, including those to clinical medicine, food science, and pharmaceutical science. Even medical diagnosis by 2-D correlation spectroscopy might be possible. For example, it is possible to investigate the effects of drugs on cancer cells by drug concentration-dependent 2-D IR spectra of the cells.

Biomolecules Analysis: Introduction

R.A. Meyers
RAMTECH Ltd, Tarzana, USA

Analysis of the various classes of biomolecules are covered in several sections of this Encyclopedia, including Biomedical Spectroscopy, Carbohydrate Analysis, Clinical Chemistry, Nucleic Acids Structure and Mapping, and Peptides and Proteins. Bioactive molecules analysis is covered in the section on Pharmaceuticals and Drugs, and some articles also directed to biomolecules can be found in the sections on Forensic Science, Environment: Water and Waste, and Industrial Hygiene.

The purpose of this section is to present bioanalytical methods which (a) are applicable to several biomolecule classes (e.g. proteins, lipids, and nucleic acids), (b) are applicable to biomembranes, cells and tissues, (c) cover chirality in biomolecules, or (d) provide analysis methods for small biomolecules (e.g. amino acids, neuromediators, and metabolites). The articles in this section contain information on sample preparation, matrix selection and detailed equipment descriptions for procedures, not covered elsewhere in the Encyclopedia.

The article on Circular Dichroism in Analysis of Biomolecules contains information on the available instrumentation for electronic and vibrational circular dichroism as well as experimental aspects for both qualitative and quantitative methods and a comparison of these methods with others for biomolecular analysis. The biomolecules treated include proteins, carbohydrates, porphyrin complexes and nucleic acid bases.

The Fluorescence-based Biosensors article includes instrumentation, interfacing biomolecules to devices, protein engineering for sensor design, applications to enzymes and enzyme-based sensors, fluorescent immunosensors, regulatory proteins, DNA-/RNA-based gene sensors, membrane-associated proteins and multi-analyte sensing.

High-performance Liquid Chromatography of Biological Macromolecules covers development modes, eluents, separation columns and chemistries, detection techniques, sample preparation and the validation of separation processes. Preferred techniques are presented for oligonucleotides, polynucleotides, peptides, proteins, and carbohydrates and their conjugates.

Infrared Spectroscopy of Biological Applications includes infrared spectroscopy of proteins, lipids, biomembranes, animal tissue, carbohydrates and plant material.

Mass Spectrometry in Structural Biology covers the use of matrix-assisted laser desorption/ionization time-of-flight in the analysis of lipids in membranes as well as proteins (collagen) and polysaccharides (e.g. glycosaminoglycans), from connective tissue and small molecules and common impurities in biological samples. Sample preparation is described and examples are given of the analysis of physiologically relevant molecules in comparison with other mass spectroscopy methods, such as electron ionization, chemical ionization, fast atom bombardment, and electrospray ionization.

The article on Nuclear Magnetic Resonance of Biomolecules contains information on instrumentation, spectral assignments and biomolecular structure determination including proteins, enzymes, nucleic acids and membranes. Information is also given on long-range distance interactions and angles.

Raman Spectroscopy in Analysis of Biomolecules presents details of sample handling and preparation, as well as the interpretation of Raman spectra with applications to amino acids and peptides, active centers in proteins, nucleic acids, lipids and biomembranes. Dynamics in biomolecules and microscopic analysis of biological systems are also covered.

The article on Single Biomolecule Detection and Characterization contains fundamental information on the interaction of light with single molecules and fluorescence correlation spectroscopy in solution, as well as the microscopy and detection of single molecules on surfaces using near-field microscopies and classical far-field microscopy. Preparation of biological macromolecules and laser micromanipulation are also covered, as is single molecule biophysics in biochemistry. The molecules analyzed include DNA in the molecular motors, kinesin, dynein, and actin.

Vibrational Optical Activity of Pharmaceuticals and Biomolecules covers the two principal instrumental forms for measuring the optical activity of biomolecules: vibration circular dichroism and Raman optical activity. Instrumentation is described from basic principles, and diagrams of typical equipment are presented. Examples include proteins, nucleic acids, and pharmaceuticals.

Voltammetry In Vivo for Chemical Analysis of the Living Brain describes electrode types and their preparation, as well as voltammetric techniques and surgical protocols. The substances targeted are neuromediators and metabolites: ascorbic acid, uric acid, dioxygen, nitric oxide, glucose, lactate, and glutamate.

Voltammetry In Vivo for Chemical Analysis of the Nervous System presents information on appropriate electrodes, recording methods, instrumentation and the preparation of cells, tissue slices, tissue pieces, and whole animals, as well as quantification and identification issues in comparison with other methods. Examples of specific bioactive compounds analyzed include dopamine, serotonin, norepinephrine and nitric oxides in cells, tissues, and whole animals.
Circular Dichroism in Analysis of Biomolecules

Petr Pančoška
University of Illinois at Chicago, Chicago, USA

Circular dichroism (CD) spectroscopy belongs to the family of chiroptical methods. These methods utilize the interaction of circularly polarized light (CPL) with chiral molecules and molecular systems to obtain more detailed information about their structure and electronic or vibrational states. CD spectrum \( \Delta \varepsilon (\nu) \) is, in fact, the difference of two absorbance spectra: one measured with the left circularly polarized light (LCPL) and the other one recorded with the right circularly polarized light (RCPL) \( \Delta \varepsilon (\nu) = \varepsilon_L (\nu) - \varepsilon_R (\nu) \). CD spectra can be measured as electronic circular dichroism (ECD) in spectral regions of electronic transitions (ultraviolet (UV)) through visible (VIS) and as vibrational circular dichroism (VCD) in the infrared (IR) spectral regions. An ECD spectrum can be also recorded as the difference excitation spectrum for fluorescence spectra excited by LCPL and RCPL, respectively (fluorescence-detected circular dichroism (FDCD)). The Raman optical activity (ROA) and circularly polarized luminescence spectroscopies complete the family of currently developed chiroptical methods. The differences \( \Delta \varepsilon (\nu) \) measured as CD are typically \( \sim 10^{-5} \) of sample absorbance. Special modifications of dispersive (for ECD and VCD) or Fourier transform infrared (FTIR) (for VCD) spectrometers are needed to measure CD with a reasonable signal-to-noise ratio (S/N). Polarization modulation of the incident light by a photoelastic modulator and synchronous electronic processing of the resulting photoelectric signal in the spectrometers are typically used for this purpose.

Molecular structure is encoded in the CD spectra because the chiral field of the CPL wave that induces a spectral transition in the chiral molecule can be observably altered both by the transition electron density redistribution (as in the conventional absorption spectroscopy) and by the transition magnetic field accompanying the molecular charge redistribution. The structure and conformation of the studied molecule define the relative orientation of the characteristic directions of these two effects. This relative orientation affects the probability of absorption of photons of RCPL and LCPL and, in turn, determines the CD sign, the primary information that is unique for CD spectroscopy. In the absolute value, CD intensity ("secondary" unique information) is related to the angle of electric and magnetic transition moments and can, therefore, be converted into the molecular conformation once the suitable theoretical model is available. For complicated molecules (biomolecules, proteins, nucleic acids) where the corresponding theoretical calculations are too complex, the empirical interpretive methods based on measurement sets of spectra measured for molecules.
with known structures (from X-ray or nuclear magnetic resonance (NMR) experiments) are used with success. For example, using these empirical methods, the fractions of regular secondary structures (secondary structure fraction (SSF)) in globular proteins can be determined with a relative error of 3–7% and the number of secondary structure segments in proteins with a typical error of one to three segments per protein fold.

CD spectroscopy is highly sensitive to the polarization artifacts that can be related to the optical imperfections of the optical parts of the spectrometer. To achieve an acceptable S/N, the sample total absorbance $A$ should be also controlled (typically $A < 0.8$). This, in effect, restricts the selection of usable solvents and largely determines the concentration ranges of studied samples.

1 INTRODUCTION

The study of differential response of molecules to circularly polarized radiation is a basis of the so-called chiroptical spectroscopic methods. The most frequently used chiroptical method is CD, which is known as ECD in UV/VIS and VCD in the IR frequency regions, respectively. The differential polarized absorption spectrum $\Delta \varepsilon (v)$ is what is measured experimentally as CD (Equation 1):

$$\Delta \varepsilon (v) = \varepsilon_L (v) - \varepsilon_R (v)$$

Here $\varepsilon_L (v)$ and $\varepsilon_R (v)$ are absorption spectra measured with LCPL and RCPL.\(^{(1-5)}\) This phenomenon is the result of a difference in the interactions of three chiral fields: that of a molecule lacking symmetry (no rotation reflection axis ($S_n$ where $n \geq 2$) can be present in its structure) and the electromagnetic fields of the two (chiral) states of the CPL (LCPL and RCPL). Similarly, the chiral molecular field of an electronically excited chiral molecule will generate unequal intensities of emitted LCPL and RCPL, upon the radiative dissipation of the excitation energy.\(^{(6)}\) There is also an observable differential Raman scattering of the photons of LCPL and RCPL by the polarizability of a chiral (i.e. optically active) molecule (ROA).\(^{(7-20)}\) This differential phenomenon of parity-even observables gives rise to the diversity of chiroptical methods.\(^{(21)}\) In this article, the discussion will be restricted to applications of ECD and VCD in biomolecular structural studies.

CD phenomena can be treated theoretically at different levels. Rotational strength $R_{oj}$ is the quantity that explains the existence of CD for any optical transition from the ground ($o$) to the excited ($j$) state of a chiral molecule. This quantity can be expressed in terms of the area under the dichroic band by Equation (2):

$$R_{oj} = 7.663 \times 10^{-54} \frac{\Delta \varepsilon (\lambda)}{\lambda} \text{d} \lambda [\text{CmJT}^{-1}]$$

where the multiplicative factor results from the evaluation of constants in the theoretical formula for rotational strength expressed in SI units.

Derivation of the theoretical representation of rotational strength can be found in classical textbooks, as well as in recent articles.\(^{(21,22-27)}\) These works have a common final result given by Equation (3).

$$R_{oj} \sim \text{Im}\langle \psi_o | \hat{m} | \psi_j \rangle \sim \text{Im} \mu_{oj} \tilde{m}_{oj}$$

Here $\psi_o$ and $\psi_j$ are wave functions of the ground and the excited states of the studied molecule, respectively; $\mu$ and $\tilde{m}$ are operators of electric and magnetic dipole moments, and $\mu_{oj}$ and $\tilde{m}_{oj}$ are the corresponding (transition) matrix elements. Because of the pure imaginary character of $\tilde{m}_{oj}$, the observable CD is related to the imaginary part (Im) of the generally complex (dot) product of the electromagnetic and magnetic transition dipoles $\mu_{oj}$ and $\tilde{m}_{oj}$. The last form of Equation (3) for the rotational strength emphasizes the relationship between the sign of the experimentally observed CD and the relative orientation of the electric and magnetic transition dipole moments $\mu_{oj}$ and $\tilde{m}_{oj}$. The CD sign is, therefore, the most informative feature of the effect.

Theoretical calculation of rotational strength from first principles is the purest way to achieve a rigorous interpretation of the experimental CD spectra. Unfortunately, the high quality of the wave function required for a reasonable quantitative comparison of calculation and experimental results restricts this possibility to relatively small molecules. However, development of quantum chemical methods is constantly moving the threshold of a “small” molecule toward larger and larger numbers of atoms.\(^{(30,31)}\) Nevertheless, approximate and empirical or heuristic methods of CD spectra interpretation remain important for large biomolecular systems such as proteins or nucleic acids, where reasonable ab initio calculational results are beyond the current computational resources.

1.1 Principles of Encoding/Decoding of the Biomolecular Features in Circular Dichroism Spectral Features

Theoretical analysis of the rotational strength allows for the recognition of the so-called mechanisms of its origin.\(^{(24,25,32)}\) These mechanisms are the dominant physical principles that convert selected structural features into the experimentally observable characteristics of CD spectra: sign, frequency at maximum, and intensity of the CD band (here ordered according to the significance of their informational content). Measurement and analysis of experimental data series on representative biomolecular sets are needed to identify the dominant
mechanism that best describes the chiroptical properties of a structurally related group of biomolecules.

This section summarizes those mechanisms that are important for biomolecular CD. Inherent chirality, the one-electron mechanism, and coupled oscillator models are based on classical analysis of rotational strength properties, which, in turn, uses the model of independent groups (chromophores). In biomolecules, these groups frequently correspond to monomers or the well-defined parts of monomers, such as amino acid residues, amide groups, side chains, nucleotides, nucleic acid bases, etc. This simplification facilitates the transfer of theoretical and experimental knowledge about the origin of rotational strength in these groups to polymers. The overall rotational strength of the whole system is then considered as a sum of the contributions from individual groups. This calculation either neglects (in the simplest approaches) or explicitly includes the effect of the intergroup interactions. Details of this approach can be found in numerous excellent papers. \(^{(33-36)}\) Selected examples are given below to help in the qualitative understanding of the multiplicity of structure-encoding principles in CD spectra. Further factors that can affect the CD spectra, including the induced CD and polymer length, are also discussed. Theoretical aspects of interpreting the rotational strength for VCD are discussed briefly.

### 1.1.1 Inherent Chirality

If a molecule is inherently chiral, the rotational strength reflects the overall chirality of the individual, independent groups (chromophores) that are defined by the asymmetry of the whole molecule. A biologically interesting example of such a system can be the disulfide chromophore with the dihedral angle of the S–S bond deviating from \(0^\circ\) or \(180^\circ\). The derivation of the relationship between that torsional angle and the CD band sign for an isolated disulfide bond transition is shown in Figure 1. Once this mechanism dominates, the experimental CD spectrum is monosignate with a maximum close to that of the corresponding absorption band. This CD spectrum might be relatively inert to changes of the substituents in the molecular structure as long as the chirality of skewed groups in the molecule is not inverted by such structural modifications.

### 1.1.2 One-electron Mechanism

In the one-electron mechanism approximation, the rotational strength can be considered to be the result of state mixing in individual achiral chromophores induced by a static perturbation of these states by the chiral molecular field. An example, explaining how the sign of the carbonyl chromophore \(n \rightarrow \pi^*\) CD band is related to the position of the substituent that breaks its symmetry, is shown in Figure 2. If this mechanism dominates the rotational strength generation, then the sign of the dichroic band in the experimental CD spectrum can be used to determine the absolute stereochemistry of chiral centers in (small) biomolecules. These simple relationships between CD sign and molecular structure are known as sector rules. Sector rules associate the sign of a band in the CD spectrum with the location of the perturbing substituent group in a space sector (quadrant, octant) that surrounds the chromophore, as is shown in Figure 2. Historically, this was the first practical structural application of ECD spectroscopy. \(^{(39)}\)

Algebraic theory of chirality functions reveals that these rules are only special cases of the general functional description of the perturbation required to induce chirality in the originally achiral molecule. \(^{(40,41)}\) In Ruch’s chirality function theory, the molecule is characterized by the point symmetry group of the achiral molecular skeleton, and by the number \(n\) of bonding sites on that skeleton that can accommodate ligands which will break the skeleton symmetry once in those positions. Algebraic analysis then determines the minimal number of different substituents needed for that to occur. This number can be found with the use of the so-called chirality function \(\Phi(\vec{L})\) parameterized by the structural descriptors \(\vec{L} = \{l_1, l_2, \ldots, l_n\}\) of the perturbing groups. The theory proves that this function describes the sign of a perturbing group contribution to the CD spectra and can determine this sign as a function of the ligand position relative to the skeleton.

A chirality function is generated by projectors based on the skeleton point symmetry group and characters of the permutation group \(S_n\), where the order \(n\) is equal to the number of bonding sites on the skeleton. The classical sector rule is meaningful only if the molecule can be characterized by the chirality function \(\phi(l_i)\), which contains terms depending exclusively on the contributions from single perturbing groups in the individual bonding sites. In a general case, the chirality function contains terms \(\phi(l_1, l_2, \ldots, l_k)\), which are dependent on the parameters of ligands from multiple bonding sites. With a molecule characterized by such a chirality function, a unique relationship of the CD band sign to a certain spatial position of a perturbing group in a space sector surrounding the chromophore cannot be simply found. An example of such a chirality function derived for an idealized skeleton of natural porphyrins is shown in Figure 3. \(^{(42,43)}\)

If a rotational strength is generated predominantly by the one-electron mechanism, the observed CD will be a monosignate band in the frequency range of the corresponding absorption peak. The CD sign will be strongly dependent on the modifications of the substituent pattern in the skeleton.
Figure 1 The mechanism by which the rotational strength is derived from the inherent chirality of the chromophore. An example of the relationship between the sign of the disulfide bond torsion angle and the sign of the dichroic band corresponding to the $\sigma \rightarrow \pi^*$ transition in this chromophore. The two $\sigma$ orbitals (a, c) and $\pi^*$ (b, d) of $\sigma \rightarrow \pi^*$ transition are shown for the two opposite values of S–S torsion angle (positive a, b; negative c, d) that are deviated from 0° and 180°. During the transition lifetime, and for both conformations, the electron density is redistributed from the bottom to the top of the chromophore as drawn. This change follows the “rule” of combination of involved orbital parts with identical and opposite phases as transition localization of partial excess and deficiency of the electron density, respectively.

The overall character of this redistribution can be described by the electric transition dipole moments $\mu_{\sigma\sigma}$ shown as arrows (e, f). The twist of the S–S bond from planarity introduces the “electron density” rotation during this transition that generates the magnetic transition dipole needed for observable rotational strength. The direction of the $\mu_{\sigma\sigma}$ can be determined by the “right-hand rule” assuming again that the rotation of the electron density follows the path of identical phases of the $\sigma$ and $\pi^*$ orbitals and the geometry of their structurally based distortions. For a positive value of the S–S torsion angle, the vectors $\mu_{\sigma\sigma}$ and $\mu_{\pi\pi}$ have parallel components (e) and, therefore, positive rotational strength is predicted (g). For a negative value of the S–S torsion angle, the vectors $\mu_{\sigma\sigma}$ and $\mu_{\pi\pi}$ have mainly antiparallel components (f) and, therefore, negative rotational strength is predicted for the $\sigma \rightarrow \pi^*$ dichroic band (h). The orbitals were calculated using the ZINDO/S method (Hyperchem v. 5.3). (37,38)

1.1.3 Coupled Oscillator Models

All of the above mechanisms require involvement of the magnetic transition dipole $\vec{n}_{\sigma\sigma}$ to produce CD. Alternatively, the rotational strength can be explained without explicitly considering the magnetic transition dipole moment in structures with repeated monomeric units of oligo- and polymeric biomolecules. In these systems, the opposing CPL interacts differently with the chiral spatial distribution of purely electric transition dipoles of monomers. If the observed rotational strength is dominated by this “coupled oscillator” mechanism, the relation of the CD sign to the structure (conformation) is given by the scalar triple product of vectors $\vec{n}_{\sigma\sigma}$ and $\vec{n}_{\pi\pi}$ and $\vec{T}_{ij} = \vec{T}_{ij} - \vec{T}_i$. These vectors represent the electric transition dipoles in the monomers $i$ and $j$, and the distance vector of the centers of mass of each $\mu_i$, respectively. The rotational strength of the coupled oscillator system can be computed in the following way:

$$R_k = -\frac{\pi}{c} \sum_{i=1}^{N} \sum_{j=1}^{N} C_{ik} C_{jk} (\vec{T}_{ij} - \vec{T}_i) \cdot (\vec{n}_{ij} \times \vec{n}_k)$$ (4)
Figure 2  Explanation of the rotational strength using the one-electron mechanism. An example of the relationship of the absolute configuration of chiral center C₁ and the sign of the lowest-energy dichroic band of the ECD spectrum of a molecule containing the carbonyl chromophore. The lowest-energy molecular orbitals of achiral cyclopenten-1-one (n, π, and π∗) are shown looking in the C=O direction at the top of the figure. The substituent X in position 2 (see structures shown at the bottom of the figure) induces mixing of n and π orbitals, which provides the magnetic transition moment necessary for observing the nonzero rotational strength. The absolute configuration of the chiral center determines both the geometrical distortion and the phase pattern of the perturbed HOMO orbital that is induced by the mixing of the original orthogonal n and π orbitals. During the transition lifetime, the electron density is redistributed from the ring towards the oxygen atom for both enantiomers. This redistribution can be described by the electric transition dipole moment $\mu_{oj}$ with the direction shown as the arrow labeled $\vec{\mu}_{oj}$ (see top view of the molecular orbitals). Distortion of the HOMO orbital by the 2-substituent perturbation introduces chirality into this transitional electron density redistribution that generates the transition magnetic dipole moment $\vec{m}_{oj}$. Its direction can be determined by the “right-hand rule” assuming that the electron density “current” follows the path of identical phases of the o and j orbitals. Consequently, the direction of $\vec{m}_{oj}$ is opposite for both enantiomers. For the (R)-isomer, the transition dipoles $\mu_{oj}$ and $\vec{m}_{oj}$ have parallel components and, therefore, a positive dichroic band is predicted. For the (S)-isomers, $\mu_{oj}$ and $\vec{m}_{oj}$ have mainly antiparallel components and a negative CD band is predicted. The orbitals were calculated using the ZINDO/S method (Hyperchem v. 5.3).\textsuperscript{37,38}

Here $C_{ik}$ and $C_{jk}$ are the eigenvector components of the dipole–dipole interaction matrix; $N$ is the number of interacting transitions; and $c$ is the speed of light. Electric transition dipoles are either determined from experimental data or calculated.\textsuperscript{34,36,44}

For regular infinite secondary structures (such as α-helices), the selection rules based on the translational symmetry of the conformation are instrumental for the simplification of the double sum in Equation (4). For example, symmetry of an idealized infinite α-helical polypeptide eliminates all but three terms in Equation (4). These terms correspond to the three observed component bands of the CD of helical polypeptides and proteins, with polarization parallel and perpendicular to the helix main axis.\textsuperscript{45,46}
stereochemical assignments for polyols and sugars, the determination of the absolute stereochemistry of applied in semiquantitative biomolecular structural stud-
tance between the interacting aromatic rings, and this dipole coupling is strongly dependent on the dis-
ions of aromatic side chains in the near UV region described by this mechanism also explains the dichroic
ments of biomolecules and nucleic acids in all explains the qualitative characteristics of the experi-
entially derived energy characteristic). The sector rule in
ions, parameter $l_i$ can be the ligand diameter or some theoretically derived energy characteristic). The sector rule in the classical form can be observed for this molecular class only if
functions $\chi(l_1,\ldots,l_N)$ vanish and only terms $\Phi(l_i)$ remain in the chirality function.

A coupled oscillator mechanism can be successfully applied in semiquantitative biomolecular structural studies. Applications relying on this mechanism range from the determination of the absolute stereochemistry of aromatic compounds, through ECD study of absolute stereochemical assignments for polyols and sugars, to the study of biopolymer conformation. The coupling of the monomer electric transition dipoles successfully explains the qualitative characteristics of the experimental CD spectra of proteins and nucleic acids in all regions. The explanation of the opposite ECD signs for an idealized dinucleotide in the $(B)$- and $(Z)$-conformations is shown in Figure 4. Dipole coupling described by this mechanism also explains the dichroic bands of aromatic side chains in the near UV region $(360-260 \text{ nm})$ of protein ECD spectra. The extent of the dipole coupling is strongly dependent on the distance between the interacting aromatic rings, and this distance is determined by the protein tertiary structure.

Therefore, the long-wavelength part of the protein ECD spectrum is primarily sensitive to this level of protein conformation.

A unique indicator of the dominance of this mechanism in the experimental CD is the bisignate shape of the observed CD with the zero crossing near the maximum of the corresponding absorption band. In an ideal, energetically degenerate case, the intensities of both exciton components of the bisignate CD should be identical. If observed experimentally, such CD is called conservative. The nonconservative bisignate CD spectra with uneven intensity of the components are measured more frequently. Intensity redistribution can be explained by the multiple mixing of nondegenerate states that determines the coefficients $C_{ij}$ in Equation (4).

1.1.4 Vibrational Circular Dichroism

The CD of vibrational transitions is weaker by one or two orders of magnitude compared with that of electronic transitions. This is a consequence of the inverse proportionality of $\Delta \varepsilon / \varepsilon$ to the wavelength. The magnetic dipole transition moment that is needed for a theoretical description of the vibrational transition rotational strength can be obtained from the derivatives of the electric dipole moment surface. These derivatives should be calculated at the equilibrium nuclear geometry with respect to the displacement of nuclei from their equilibrium positions. The vibrational magnetic transition moment is related to the transition electron currents associated with the vibrational transition. The corresponding theoretical matrix elements are thus linearly related to the relative velocities of the vibrating nuclei. Although there have been attempts to produce pictorial descriptions of VCD mechanisms, they were unsuccessful because of their limited validity. A nondegenerate coupled oscillator mechanism can be used for semiquantitative structural analysis of the VCD of biopolymers such as nucleic acids and peptides.

1.1.5 Induced Chirality

In addition to the induction of optical activity by the application of external electrical or magnetic fields (Kerr effect, magnetic circular dichroism (MCD)) archiral molecules can become optically active through specific bonding to chiral counterparts (molecular matrices). An ordered and site-specific spatial relationship between the achiral molecule and its chiral molecular host is a necessary condition for observation of this so-called induced CD. The relative orientation of the chromophore and the host should be uniform in all realizations of such a specific supramolecular system in the solution, otherwise the variable signs of induced CD would lead to the
Figure 4 The use of a coupled oscillator mechanism to explain the origin of rotational strength. (a, b) The orientation of two neighboring bases in a polynucleotide in the (B)- and (Z)-forms. Arrows show the relative orientation of identical parts of the base structure. Full-line and dotted-line arrows are closer and more distant to the viewer, respectively. The opposite handedness of the two helical secondary structures is also shown using the ladder rendering (c, d). Perturbation of the degenerate electronic states of individual bases \( i \) and \( j \) generates two new states \( i' \) and \( j' \). One has higher and the other has lower energy than the degenerate original states. During the electronic transition, the higher-energy state corresponds to the parallel orientation of the electric transition dipole moments; the lower-energy state corresponds to their antiparallel orientation (e). Relative spatial orientation of the two transition electric dipoles \( \mathbf{E}_i \) and \( \mathbf{E}_j \) defines the directions of the distance vector \( \mathbf{r}_{ji} \) and the vector product \( \mathbf{E}_j \times \mathbf{E}_i \), respectively, that are needed for the determination of the sign of their scalar triple product, yielding the sign of the corresponding rotational strength. For the (B)-form (f) of the polynucleotide conformation, the exciton component of the bisignate dichroic band at shorter wavelength is negative. The triple product in this case is positive because the components of the \( \mathbf{r}_{ji} \) and \( \mathbf{E}_j \times \mathbf{E}_i \) vectors are parallel and rotational strength has the opposite sign to the triple vector product \( \mathbf{r}_{ji} \cdot (\mathbf{E}_j \times \mathbf{E}_i) \) (see Equation 4). Using the same arguments, the exciton component at longer wavelength is predicted to be positive. The opposite signs of the corresponding components are found for the (Z)-form (g) as a result of the reversed chirality of the vectors in the \( \mathbf{E}_j \times \mathbf{E}_i \) product. The predictions are in agreement with the experimental CD spectra of these DNA conformations.
effective cancellation of the dichroic intensity. Examples of well-defined complexes that exhibit strong ECD upon formation are dye molecules that intercalate into a double helical nucleic acid host; carotenoid molecules fixed on the protein matrix in photosynthetic chlorophyll–protein complexes; or complexes of cationic tetraphenyl porphyrins with sequential basic polymeric di-, tri-, and tetrapeptides. Although theoretically possible, induced VCD has not yet been studied.

The dependence of induced CD on the molecular geometry and the chromophore interaction energy with the host matrix was theoretically analyzed using general symmetry and parity arguments. The magnitude of the magnitude difference was predicted for the induced CD of two mirror image geometries of the complex. This difference is modulated by the weight factor, depending on the interaction energy between the two parts of the chiral complex. A schematic explanation of this result is shown in Figure 5.

1.1.6 Length Dependence

There is yet another structural feature that can influence CD spectra of polymeric biomolecules. The CD intensity for these molecules depends nonlinearly on the biopolymer length, defined in terms of its monomeric unit number $N$. Taking this effect into account improved the quantitative predictions of SSF from ECD spectra.

The correction of the component spectra according to the length of the analyzed protein was implemented as an empirical function $1 - C(i)/N$, which modifies the ECD band amplitude. Here, $C$ is the wavelength-dependent parameter that is optimized experimentally. Theoretical analysis of this phenomenon showed that the above empirical function is only a special case of a more general

$$\Delta R = \frac{1}{2N} \left( \sum_{s} \left( \phi_{s}^{R} + \phi_{s}^{L} \right) \left( \langle \phi_{s}^{R} | \hat{R} | \phi_{s}^{R} \rangle + \langle \phi_{s}^{L} | \hat{R} | \phi_{s}^{L} \rangle \right) \right)$$

where $\phi_{s}^{R}$ and $\phi_{s}^{L}$ are wave functions characterizing the porphyrin in R- and L-orientation, respectively, and $\rho_{s}^{R,L}$ terms are density matrix elements for the states $s$ and $s'$. $\Delta R$ is the direct consequence of this relation. The limit of this equation is only a special case of a more general

$$\sum_{s} \left( \phi_{s}^{R} + \phi_{s}^{L} \right) \left( \langle \phi_{s}^{R} | \hat{R} | \phi_{s}^{R} \rangle + \langle \phi_{s}^{L} | \hat{R} | \phi_{s}^{L} \rangle \right)$$

Figure 5 Induced chirality of ordered molecular complexes of an achiral chromophore with a chiral polymeric matrix. Experimentally, induced CD in porphyrin transitions was observed for anionic and cationic tetraphenyl porphyrins complexed with polycationic sequential polypeptides and polynucleotides, respectively. (a) An idealized example is shown of the two complexes of an achiral porphine and $\alpha$-helical polypeptides poly(L-Lys-L-Ala-L-Ala) and poly(L-Lys-L-Ala-L-Ala-L-Ala). The different helicity of the L-lysine side chain distributions on the backbone structure generates the enantiomorphic orientations R and L of the pigment with respect to the direction of the polypeptide helix (arrows in the two complexes). (b) A theoretical analysis of the difference in the induced rotational strength for the two conformations $\Delta R$ using the derived formula shows that this difference is dependent on the strength of the interaction between the chromophore and the peptide (density matrix elements $\rho_{s}^{R,L}$ are directly related to that interaction energy) that modulates the sum of the rotational strength operator matrix elements for the states $s$ and $s'$.

Figure 6 Steps in the derivation of length dependence of rotational strength (Equation 5). (a) The infinite length polypeptide is partitioned into two types of segments: those with the length $N$ and those with length $M(N \gg M)$. (b) $M$ is chosen in such a way that if the $M$-segment is removed from the chain, there is no interaction between the isolated $N$-segments. (c) This “structural” partitioning transforms the Hamiltonian of the system into the block-diagonal form where $H_{11}$ and $H_{22}$ describe $N$-segments and $M$-segments, respectively. In this form, the negative eigenvalue theorem$^{(45)}$ can be used to calculate the integrated density of states $I_{N}$ corresponding to the Schrödinger equation with this Hamiltonian and given $N$. The limit of this solution for $N \to \infty$ regenerates the integrated density of states $I_{\infty}$ and the basic inequality (d) is proven to hold. Equation (5) is the direct consequence of this relation.
functional form.\(^{(45)}\) Figure 6 summarizes the background information for the physical basis of the derivation of the final formula. According to this formalism the length dependence of rotational strength \(R_{\alpha j}(\lambda, n)\) is

\[
R_{\alpha j}(\lambda, n) = R_{\alpha j}(\lambda, \infty) \left(1 + \sum_{i=1}^{n} \frac{C_i(\lambda)}{N^i}\right)
\]

Here, \(R_{\alpha j}(\lambda, \infty)\) is the rotational strength of a given transition for an infinitely long polymer and \(C_i(\lambda)\) are adjustable parameters, usually determined experimentally. Equation (5) extends the applicability of this intensity correction for chiroptical methods other than ECD. It was shown, in a comparative study of ECD and VCD of proline oligopeptides with systematically varied length, that VCD requires third-order terms in Equation (5) in order to achieve acceptable fit of observed intensity variation in amide I vibration. For the same peptides, the ECD intensity length dependence was satisfactorily described only by the first-order term.\(^{(68)}\)

For proteins, it is more appropriate to interpret \(N\) in Equation (5) as the average length of the backbone segments folded into a given type of secondary structure. As a consequence of this effect, the CD of two proteins might be different even if they have identical secondary structure compositions distributed over a different number of segments (see Figure 7).\(^{(69,70)}\)

### 1.2 Advantages and Limitations

If the structural problem in hand is qualitative, then the sign of the experimentally observed dichroic bands in any frequency region contains usually all the information that is needed. Examples of such applications are the differentiation between enantiomers, detection of opposite chirality in biopolymer regular structures (e.g. of \((B)\)- and \((Z)\)-conformations of nucleic acids), or any observation of induced CD.

The ability to observe CD is governed by unique selection rules that are different from those for absorption. Although this, in principle, leads to an observation of forbidden absorption transitions in CD, the dissymmetry of biomolecules reduces the importance of this CD advantage.

In spectral bands that are combinations of overlapping components, for example the IR regions of amide I or II where the protein amide group vibrations absorb, the differences in the CD signs can facilitate the identification of such components. Such a qualitative identification of

![Figure 7](image-url)
a component that would be difficult to recognize in an ordinary absorption spectrum represents again the most effective application of CD spectroscopy. Attempts to utilize this qualitative advantage of CD quantitatively require deconvolving the CD spectral envelope into the signed component bands. This is a task that has perhaps even more serious algorithmic problems than the deconvolution of the corresponding absorbance spectra. The uncertainties in the determination of parameters of mutually canceling signed bands are serious and even the additional restrictions when CD and absorbance spectra are deconvolved simultaneously cannot significantly improve the situation.

Efficient methods of quantitative analysis of biomolecular CD spectra benefit primarily from the increased variability of the spectral bandshape given by the addition of sign to absorption bands. In this respect, the introduction of VCD was a major development because of the additional structural sensitivity of vibrational transitions. Besides their sign, the frequency at the maximum of dichroic bands in the IR region depends very specifically on the structure in general and on the conformation of biomolecules in particular. This facilitates, for example, better differentiation of helical and sheet spectral components of proteins by VCD than by ECD.

Of all chiroptical methods, the ECD is the best established spectroscopic technique with commercially available instrumentation. In most biomolecular studies, ECD transitions are broad, heavily overlapped, and sensitive to relatively global structural features. The studied molecule undergoes a transition from a ground to an excited electronic state. ECD measurement typically requires about 2 mg or less of a biomolecular sample per experiment. The spectral region is accessible from 180 to 600 nm, which can be expanded to ~1000 nm with a photomultiplier change, which often requires a subsequent baseline realignment. The main experimental limitation for ECD measurement is the sample absorbance. It must be below 1.0 absorbance units for most CD spectrometers to ensure sufficient photon flux on the detector. Besides the oscillator strength of the studied biomolecular transitions, it is the choice of the solvent or buffer components that also interferes with the ECD detection below 220 nm. In a typical setting, the ECD measurement is relatively fast. It usually takes about 30 min to complete the experiment including the sample preparation and data pretreatment and storage. With a special attachment, ECD spectrometers can be used as selective detectors in chiral separations by high-performance liquid chromatography (HPLC).

VCD instrumentation is commercially available in the FTIR variant, and numerous dispersive instruments were built from commercial components in research laboratories. In both variants, the details of the spectrometer optical design are very important. The differential absorption in the IR is 10–100 times smaller than the typical CD in the UV region, and the measured signal is, therefore, prone to a broad range of polarization artifacts. Transitions in the IR are generally well resolved and the studied molecules remain in the ground electronic state during the measurement. A VCD experiment typically requires concentrations of 50 mg in 2 mL while the practical sample volume needed for two or three measurements is about 100 µL. The concentrations of biomolecular samples measured in water solvents are even higher. Current VCD spectrometers can operate in the mid-IR spectral region (600–4000 cm⁻¹). The possibility of measurements in the other frequency regions requires a new design for the polarization optical elements and corresponding detector changes (see below). To obtain an acceptable S/N, the measurement is proportionally slower than in ECD, but this difference will become less important with further technical developments in VCD instrumentation. Absorption of the solvent, or buffer component, poses a more serious problem in VCD than in ECD. Absorption of water, which is the typical solvent in biomolecular studies, in the IR overlaps with the characteristic absorbance of proteins and nucleic acids. Deuteration of the solvent can open the needed spectral window but can also alter the vibration modes of the molecule involving exchangeable protons. This requires special attention, as incomplete deuteration in the solvent-inaccessible regions of biopolymer structures might complicate the VCD spectrum. Under controlled experimental conditions, deuteration can be used as an additional factor in obtaining novel structural information.

2 HISTORY AND AVAILABLE INSTRUMENTATION

Differential absorption of RCPL and LCPL can be measured directly using the definition of CD in Equation (1) in an instrument that controls the state of the probing CPL. This principle is the method of choice in commercial CD spectrometers. Another physical observable that can be used to determine CD is the ellipticity of originally linearly polarized light after the interaction of its circularly polarized components with a circularly dichroic sample. The principal advantage of this approach compared with the previous method is its practically instantaneous response time, allowing measurements at the sub-microsecond level. This makes the method attractive for time-resolved CD spectral measurements even though it is technically more difficult. Only the first technique will be discussed further.

It is customary to characterize the differential response of a chiral sample to LCPL and RCPL by the dissymmetry
The term $g$ is the maximum modulator retardation and flux signals to the input total light intensity (Equation 7):

$$I(v, t) = I_{DC}(v) + I_{AC}(v) \sin[\delta_{\text{MAX}}(v) \sin(\omega_{M}t)]$$ (6)

The term $I_{DC}(v)$ is proportional to the absorbance of the sample, including the contribution from the instrument parts. The sine-of-sine function describes details of the time dependence of the state of the probing CPL ($\delta_{\text{MAX}}(v)$ is the maximum modulator retardation and $\omega_{M}$ is the modulation frequency). Equation (6) can be rearranged into the following form that describes the change in CD with a photoelastic modulator by introducing Beer’s law relating direct current (DC) and alternating current (AC) light flux signals to the input total light intensity (Equation 7):

$$\Delta\varepsilon(v) = \frac{g_{AC}}{g_{DC}} \frac{2}{2.303} J_{1} [\delta_{\text{MAX}}(v)] \frac{I_{AC}(v)}{I_{DC}(v)}$$

$$= K(v) \frac{I_{AC}(v)}{I_{DC}(v)}$$ (7)

Here $g_{AC}$ and $g_{DC}$ are amplification gains for the two signals, respectively, and $J_{1}$ is the first-order Bessel function describing the fundamental frequency selection from the composite time dependence of the circular polarization (Equation 6) that is accomplished by the selective lock-in amplifier tuned to $\omega_{M}$. The optimization of the instrument constant $K(v)$ is performed at every frequency by the voltage $U_{s}$ derived from the monochromator wavelength that adjusts the retardation $\delta_{\text{MAX}}$. The term $K(v)$ also includes the instrument function, which is normally determined by calibration.

### 2.1 Single Beam Electronic Circular Dichroism Spectrometer

Figure 8 shows the basic features of the ECD spectrometers available commercially. These use powerful light sources with intense radiation in the UV, which is the region of primary interest for biomolecular studies. The water-cooled high-pressure 250–450 W xenon discharge lamp is common. The light from the source is collected with a mirror and monochromatized. In the classical design, monochromators use a prism simultaneously as a dispersive and polarizing optical element. Only half of the total light intensity is used after the linear polarization of the probing light (the extraordinary ray is blocked). The linearly polarized and monochromatized light is converted into the alternatively left and right circularly polarized forms by a quartz photoelastic modulator before it enters the sample cell. The output light intensity is detected by the photomultiplier and the resulting signal is processed after preamplification by the detection electronics (lock-in) tuned to the photoelastic modulator carrier frequency. To facilitate processing, the $I_{DC}$ part of the signal (Equation 6) is usually kept constant by real-time variation of the photomultiplier gain $g_{DC}$.

### 2.2 Dual Beam Electronic Circular Dichroism Spectrometer

An alternative design for a CD instrument, introduced by Olis (Bogart, GA), is shown in Figure 9. After the

![Figure 8](image-url)
Figure 9 The dual beam spectrometer for ECD measurement. S, light source; M, grating monochromator; P, polarizer; PEM, photoelastic modulator; PMT1 and PMT2, photomultipliers; A/D amp, conversion of the analog signal into the digital form; bitL,R, information about the modulation state of the light used to tag the converted photocurrents; Uₗ, optional voltage ramp derived from the monochromator state and used to adjust the PEM modulation Uₗ/4 to λ/4; v-drive, signal for stepping motor of the monochromator; Uₗ, voltage derived from the IᵥDC part of the photoelectric signal of PMT that is used to control the gain of PMT as needed for an effective analog-to-digital conversion.

wavelength selection by a grating monochromator, the photoelastic modulator modulates both ordinary and extraordinary linearly polarized light beams emerging from the MgF₂ Rochon polarizer. These two beams are at any given time in the oppositely circularly (or elliptically) polarized states through the perpendicular relative orientation of their linear polarization planes. In particular, when one beam is RCPL, the other one is LCPL and vice versa (see Figure 10a). The optical design ensures that both beams are passed through the sample cell, where the polarization modulation is converted into intensity modulation. The signals I₁ and I₂ that are independently detected by two photomultipliers can be described as

\[
\frac{I₁}{I₀₁} = \frac{1 + Q(\nu)}{2} e^{i(\nu)(1 + \Delta \varepsilon(\nu) \sin(\delta_0 \sin(wₘt)))} \quad (8a)
\]

\[
\frac{I₂}{I₀₂} = \frac{1 - Q(\nu)}{2} e^{i(\nu)(1 - \Delta \varepsilon(\nu) \sin(\delta_0 \sin(wₘt)))} \quad (8b)
\]

where I₀₁ and I₀₂ are input total intensities measured by detector 1 and 2, respectively; Q(\nu) is Stokes parameter describing the effect of beam linear polarization, and \(\varepsilon(\nu)\) and \(\Delta \varepsilon(\nu)\) are overall absorbance and CD, respectively. Other symbols have the same meaning as in Equation (6).

To maximize the advantage of this design, which provides simultaneous information about the CD of the sample at any time point, the averaging strategy is modified. The signals from both photodetectors are converted into digital form by two fast 14-bit analog-to-digital converter (ADC) circuits. Their 400 kHz conversion rate yields eight data points per cycle at 50 kHz modulator frequency. The most significant bit of each record is set to 1 or 0, indicating the state of the probing light (LCPL or RCPL) derived from the reference frequency of the photoelastic modulator (bitL,R, Figure 9). The signals I₀₁ and I₀₂ are first used to normalize the intensities measured by individual detectors at each wavelength. The records corresponding to the RCPL and LCPL probing light beams are then averaged independently on the detector. The algorithm

Figure 10 (a) Time dependence of the circular polarization modulation in the ordinary \((1 + \sin(\delta))\) and extraordinary \((1 - \sin(\delta))\) light beams of the dual beam ECD spectrometer. (b) The differences in the two optical channels of the dual beam ECD spectrometer (a simple multiplicative difference between the signals of photomultipliers 1 and 2) is compensated by the spectrometer-averaging algorithm (see text for details).
uses only their digital tags for L and R recognition; consequently one-half of the data come from channel 1 and the other half from channel 2. The \( Q(v) \) dependency in Equation (8) is effectively canceled by this averaging mode. CD is then calculated (Equation 9) using the ratio of determined RCPL and LCPL record averages

\[
I_{R/L} = \frac{e^{-\Delta \varepsilon(v)} - 1}{2} \int_{T/2}^{T} \sin(\delta_0 \sin(w_m t)) \, dt
\]

\[
= \frac{e^{-\Delta \varepsilon(v)} - 1}{2} (1 \pm \Delta \varepsilon(v) \sin(\delta))
\]  

(9)

Here, \( \sin(\delta) \) is the frequency-dependent constant defined as the mean value of the functional description of modulation function. The final expression (Equation 10) describing this variant of CD assessment is derived from Equation (9) using the approximate formula for logarithms of small \( \Delta \varepsilon(v) \) values:

\[
\Delta \varepsilon(v) = \frac{1}{0.8686 \sin(\delta)} \log \frac{g_R I_{L_0}}{g_L I_{R_0}} = K(v) \log \frac{I_L}{I_R}
\]

(10)

There are several theoretical advantages of this CD measurement mode. First, the cancellation of the linear dichroism term \( Q(v) \) justifies the use of the grating monochromator. The effect of the wavelength-dependent linear polarization of the probing light after the monochromatization by a grating is minimized. Second, the averaging mode ensures relative insensitivity of the CD to the fluctuations of the two photodetector signals. For example, if the signal level detected by one photomultiplier drops by a factor \( k < 1.0 \) (see Figure 10b), the averaging mode compensates for this difference in the two channels in the following way:

\[
\Delta \varepsilon(v) = K(v) \log \frac{\sum_{i=1}^{N} I_{L_1} + k \sum_{i=1}^{N} I_{L_2}}{\sum_{i=1}^{N} I_{R_1} + k \sum_{i=1}^{N} I_{R_2}}
\]

\[
= K(v) \log \frac{(1 + k) \sum_{i=1}^{N} I_{L_i}}{(1 + k) \sum_{i=1}^{N} I_{R_i}}
\]

\[
= K(v) \log \frac{\sum_{i=1}^{N} I_{L_i}}{\sum_{i=1}^{N} I_{R_i}} = K(v) \log \frac{I_L}{I_R}
\]

(11)

Similar argument holds even for more complex variations of signals in both channels. In these cases, the averaging mode effectively replaces the functional description of the fluctuation by the numerically determined mean values of that function. Constant values cancel out in the way described above.

Utilization of both ordinary and extraordinary light beams results in more effective use of the light source energy. There is, nevertheless, still restriction on the sample absorbance. The changes of the light intensity by the sample absorbance are compensated by the feedback variation of the high voltage on both photomultipliers. This is necessary for optimal use of the full digital range of the ADC. This instrument also offers selection between the classical monochromator and the rapid scanning, subtractive, double-grating monochromator with moving intermediate slit. In the classical variant, the maximal retardation of the photoelastic modulator is optimized for the output wavelength. In the rapid scanning mode, the wavelength change is too fast for the modulator to follow. The retardation is, therefore, set to be optimal for median wavelength of the scanned interval. The CD intensity is computationally corrected using a calibration curve as described below for VCD.

2.3 Dispersive Vibrational Circular Dichroism Spectrometer

There are two experimental set-ups for a measurement of VCD, the dispersive and Fourier transform (FT) instruments. In the former, the basic experimental scheme is the same in many aspects as that described for ECD spectrometers. A change of the frequency region dictates a replacement of the light source, the materials of the optical elements, and the detectors for operation in the IR spectral region. In the latter the interferometer of the FT instrument is used as the source of light. The interferometer introduces a modulation of the intensity of low frequencies that encodes the optical frequencies. The FT spectrometer is then extended by optical elements for high-frequency polarization modulation and by the additional electronics necessary for the detection of the weak-intensity modulation at the high frequency that is attributed to sample VCD.

The scheme of a generic dispersive VCD spectrometer is shown in Figure 11. The light sources that are used in practice include a high-temperature Nernst glower (64,85,87) or a carbon rod heated in an inert atmosphere to \( \sim 2400 \, K \) (3,74,75). After the light has passed through the collection optics, the light intensity is modulated at low frequency (\( \sim 100–200 \, Hz \)) by a mechanical chopper to improve the detection of signal \( I_{DC} \) corresponding to the sample absorbance. A grating monochromator, wire grid polarizer (typically on BaF\(_2\) substrate), and photoelastic modulator with either CaF\(_2\) or ZnSe crystals are used to prepare the probing light with high-frequency (\( \sim 32 \, kHz \))
modulation of its circularly polarized state. These materials have operation optima at ~1200 cm\(^{-1}\) and ~1000 cm\(^{-1}\) respectively and cutoff lower frequencies at ~600 cm\(^{-1}\). Barium fluoride is a sample cell material that is suitable for the water-based solutions used in biomolecular studies. The light is detected by the semiconductor detector, which is cooled by liquid nitrogen. Mercury cadmium telluride is a sample cell material that is suitable for mid-IR to ~400 cm\(^{-1}\) whereas InSb is used for the near-IR. After amplification, the signals carried by low- and high-modulation frequencies are separated by two lock-ins. One amplifier operates at the reference frequency of the photoelastic modulator, the other at the chopper frequency. The two signals representing the transmission intensity and the polarization modulation intensity are processed in the dynamic normalization circuit. Alternatively, they can be separately put through an ADC and their ratio is then calculated numerically by the processing computer. These procedures replace the dynamic normalization by the photomultiplier gain in the ECD, which is impractical for semiconductor IR photodetectors. The ratio of AC and DC signals is scaled by the calibration factor \(K(v)\) determined from the calibration procedure (see below), and the resulting VCD spectrum is stored.

### 2.4 Fourier Transform Vibrational Circular Dichroism Spectrometer

A generic FT spectrometer for VCD measurement is shown in Figure 12. A light from the IR source passes through the interferometer, which encodes the frequency information into the (low-frequency) intensity modulation. This light is then modulated at 30–50 kHz in a polarizer–photoelastic modulator optical system that is identical to that in the dispersive VCD spectrometer. After passing through the sample, the light is focused on the large-area semiconductor detector cooled by liquid nitrogen. Use of a lens for this purpose allows covering and integrating the signal uniformly over the photodetector active area. This reduces the sensitivity of the spectrometer to optical artifacts.\(^{91}\) A signal from the photodetector is amplified and separated into the low- and high-frequency components. This step requires special care (use of filters and optimal gain selection) to avoid saturation of the spectrometer detection system and overloading of the processing electronics. A digitized low-frequency signal is processed by the standard FT routines to provide the \(I_{DC}\) part of Equation (7). The high-frequency signal is further selectively amplified by the lock-in that is tuned to the photoelastic modulator frequency. The resulting signal is fed into the special FT routines that determine the \(I_{AC}\) component of Equation (7). The interferogram defined the \(I_{AC}\) signal can be understood as the difference of the two interferograms corresponding to the absorbance spectra for oppositely CPL. Standard routines for the fast FT localize the zero path difference (ZPD) point of the interferogram using the unique intensity of the center burst. This causes problems for the difference interferograms representing VCD, which have the center burst area generally weak. Either an experimental or computational correction of the ambiguity of ZPD determination is needed.\(^{92}\) In the FT calculation, the transferred phase algorithm is used. The required phase function can be determined experimentally using the stressed optical (ZnSe) plate instead of the sample and stored.\(^{13}\) After the transformation of interferograms, the computer calculates the
VCD spectrum as the ratio of the $I_{AC}$ and $I_{DC}$ signals and scales it by the proper calibration factor (see below) corresponding to Equation (7). A variant of this “fast-scan” spectrometer was also developed for the step-scan FTIR spectrometers.\(^\text{(93)}\)

2.5 Developmental Designs

2.5.1 Instruments and Methods

CD spectra can also be monitored by measuring the difference in the luminescence intensity that is emitted from a chiral sample after excitation by CPL. This technique is called FDCD; Figure 13 shows a typical design scheme.\(^\text{(25)}\) In the FDCD apparatus, the excitation monochromator, polarizer, and photoelastic modulator are used to prepare light with alternating circularly polarized modulation. This light excites the fluorescence of the chiral molecule. The detection end of the optical system, where, optionally, the emission wavelength can be selected by the emission monochromator, collects emitted light. The fluorescence intensity is detected by the photomultiplier. After amplification of the photosignal by a lock-in that is in phase with the photoelastic modulator frequency, the $I_{AC}$ and $I_{DC}$ components of the signal are ratioed and a CD spectrum is obtained. There is no signal outside the absorption band in all luminescence-based methods where, by comparison, absorbance techniques have high light intensity throughput. Modifications of the detection scheme are, therefore, needed to handle this trend of the $I_{DC}$ signal.\(^\text{(6)}\)

The potential advantages of FDCD are the possibility of measuring CD spectra for samples that are heavily light scattering and for selective measurements of CD spectra of components of a mixture, provided that there are sufficient spectral separation and a high quantum yield of their fluorescence. It is essential for the interpretation of FDCD spectra that they still represent the CD spectrum of the ground state of the studied molecule.

The conformation of the excited state of a molecule can be examined using the spectral dependence of emitted CPL (Figure 14).\(^\text{(6)}\) This instrument detects the difference in magnitudes of oppositely CPL components that are emitted by the chiral molecule. The photoelastic modulator and polarizer have an inverted role in this spectrometer compared with previous designs described. Here the photoelastic modulator converts circularly polarized components of the luminescence into modulated linear polarization of the emitted light. The polarizer in its proper orientation then converts this polarization into the intensity modulation that is processed by the lock-in amplification scheme in phase with the photoelastic modulator frequency. Alternatively, the dual modulation scheme with chopper, additional lock-in, and dynamic or computational normalization of absorbance and CD signals can be used.

CPL emission spectroscopy is the unique tool for excited-state structural and dynamic studies. Other promising areas for the applications of this technique are the enantioselective quenching of racemate luminescence by chiral quenchers and applications benefiting from the selectivity and unique physical mechanisms responsible for the luminescence phenomenon.

2.5.2 Spectrometer Components

The principal motivation for designing novel optical components for CD spectrometers is the attempt to broaden the spectral region in which CD spectra can be measured.
The far-IR region (below 600 cm\(^{-1}\)) is one of the targets of these innovations. The 600 cm\(^{-1}\) low-frequency limit of current VCD spectrometers is principally a consequence of the combination of optical and mechanical properties of the IR-transparent materials that can be used as crystals in the photoelastic modulator. Two alternative techniques were tested as a basis for the replacement of the photoelastic modulator: the spinning quarter-wave plate polarization modulator and the polarizing interferometer. The principal scheme of the polarizing interferometer is shown in Figure 15.\(^{(98)}\)

The key part of this design is the beam splitter, which is made of properly transparent optical material and covered by a polarizing grid. This addition makes the beam splitter transparent only for one light linear polarization state (S in Figure 15) while the other polarization, P, is reflected. Interferometer mirrors acts as the “retro-mirrors” that change the original polarization state of the light returned by them. Figure 15 explains the role of the polarizing beam splitter in bringing two perpendicularly linearly polarized beams to the coherent combination at the interferometer output. Periodic translation of the movable mirror introduces the phase retardation of these two polarized beams. Circular polarization of the monochromatic light is thus generated when the path difference equals \((4k + 1)\lambda/2\) (LCPL) and \((4k + 3)\lambda/2\) (RCPL), \(k = 0, 1, \ldots\). The practical application requires a signal-processing method that properly selects interferogram components corresponding to these frequencies and an exceptionally stable spectrometer design.\(^{(61)}\)

Another design of the polarization modulator brings an additional degree of flexibility beyond the frequency region extension. Its construction utilizes the simple fact that rotation of the quarter-wave plate perpendicularly to the path of the linearly polarized light produces variation in the circular polarization state twice within one full rotation cycle.\(^{(86,87)}\) The mechanical design requires stable and virtually friction-free rotation of the plate with a frequency in the kilohertz range. This was achieved by modification of the design of the air-driven turbine that is used to spin the sample in NMR spectrometers (Figure 16). In addition to the possibility of varying the optical materials that can be used as the quarter-wave plate, this design offers the unique possibility of continuous variation of the modulation frequency simply by changing the pressure of the propeller gas.\(^{(86)}\)

### 3 GENERAL EXPERIMENTAL ASPECTS

#### 3.1 Instrument Calibration Procedures

The CD spectrometer needs calibration in all the above modifications. This is equivalent to the determination of the frequency-dependent constant \(K(v)\) in Equations (7) and (10). Measurement of a standard sample with known dichroic properties is one alternative that is used for this purpose. A water solution of \(d\)-10-camphorsulfonic acid is now generally accepted as the calibration standard for classical ECD spectrometers.\(^{(5,4,71,86)}\) With this element replacing the sample, an intense CD signal is measured that can be described as

\[
\frac{I_{AC}(v)}{I_{DC}(v)} = \frac{\pm 2 J_2(\delta_{\text{MAX}}(v)) \sin[\delta_{\text{BP}}(v)] g_{\text{AC}}}{1 \pm J_1(\delta_{\text{MAX}}(v)) \cos[\delta_{\text{BP}}(v)] g_{\text{DC}}} \tag{12}
\]

with symbols having the same meaning as in Equation (7) and with different signs for different relative orientations of the birefringent plate and the polarizer. The points of equal intensity can be found for the pairs of formulae with proper choice of signs in Equation (12). As can be proved

---

**Figure 15** The polarizing interferometer. \(S\), light source; PBS, beam splitter with polarizing grid that makes it transparent only for \(S\)-polarized state of the light; \(S_1, S_2, P_1,\) and \(P_2\), polarization elements. Note the change of the polarization state at the mirrors.

**Figure 16** The spinning quarter-wave plate polarizer. Optical material of the plate is stressed in the stress frame, forming the quarter-wave retarder \(\lambda/4\). Propeller gas is used to spin the plate holder. The reference signal \(f_{\text{mod}}\) is derived from the light-emitting diode–PIN photodiode pair and chopper-like blade on the spinning plate holder.
by algebraic manipulation of the above equation together with Equation (7), the intensities of the calibrating device CD at these nonzero crossings are equal to the respective values of the $K(v)$. Practically, the intensities of the calibration signal at the midpoint between any two of its zero-crossings can be used as the $K(v)$. This follows from analysis of Equation (12) and eliminates the need for readjustment of the calibrating device. The same procedure is applicable for both dispersive and FTIR CD instruments. The advantage of this approach over the single- or even two-point calibration with a standard solution is that it can provide the calibration values as a function of wavelength. Calibration of a different kind is needed for the rapid-scanning dual beam ECD spectrometer where the maximum retardation of the photoelastic modulator cannot be wavelength-adjusted during the fast spectrum scan. The CD intensity has to be corrected in this case for the imperfections in the polarization state of the probing light over the measured frequency interval. Because of the described unique character of the data processing, no intensity calibration in the classical sense is needed for this spectrometer in either normal or rapid-scanning operational mode.

### 3.2 Sampling Techniques

There are numerous instrumental and practical aspects of ECD measurement that might affect the quality of the measured spectra. The lifetime of the light source is limited typically to about 1000–2500 h of operation. Degradation of the lamp output results in lower S/N and reduction in accessibility of the shortest wavelengths. It is recommended that the light throughput of every ECD spectrometer is continuously monitored in the well-defined state. Using the readings of the photomultiplier ECD spectrometer is often significant for biopolymer samples and requires thorough cleaning of the cells in chromosulfuric acid or for largely cationic solutions in basic solutions. Checking the pH of the solution used to wash the cell after this treatment is a surprisingly sensitive indicator of the completeness of the cleaning process.

As the ECD spectrometer operates in the single beam mode, the position and orientation of the cell during the baseline and sample scan should be identical. Dependence of the ECD spectrum shape on the distance of the cell from the photomultiplier might indicate light scattering on the aggregates of the solute. A combination of the sample concentration and the cell pathlength is used to adjust the sample absorbance to 0.6–0.8. Artifacts related to the low light intensity and high gain on the photomultiplier are observed for higher absorbances.

As the instrumentation for VCD measurements is less standardized, the experimental protocols depend on the particular spectrometer. In the FTIR instruments, the saturation of the sensitive semiconductor detectors by the high light throughput might require use of optical filters, which reduces the multiplex advantage of this technique.

The successful measurement of VCD of biological samples requires careful choice of the solvent and cell window material and the cell construction. Windows of BaF$_2$ separated by Teflon or Mylar spacers and either demountable or refillable cells have been used for protein, peptide, and nucleic acid VCD studies. The absorption of water or D$_2$O, which is a common solvent for these studies, dictates the small pathlengths (50 µm for D$_2$O and 6 µm for H$_2$O solutions). Demountable cells require typically 20–30 µL of 50 mg mL$^{-1}$ concentrated protein solution in D$_2$O. Refillable cells are used for measurements with water solutions (more than 100 mg mL$^{-1}$ protein is needed for separation of the solvent and protein signals) and may require proportionally larger sample volume. Demountable cells without spacers have been used.

Baselines for VCD measurements are generally recorded under experimental conditions identical to those of the sample with a solvent-filled cell. Alternatively, a solution of poly(L,D)-lysine with the absorbance at 1650 cm$^{-1}$ adjusted to match that of the measured sample can be used to minimize the impact of the absorption-related artifacts in protein VCD studies. Simultaneous measurements of IR absorbance of the VCD sample allow normalization of the measured VCD sensitivities ($\Delta A \sim 10^{-7}$). Highly volatile solvents (e.g. methanol) should not be used for cell washing as the heat of evaporation induces measurable strain in the quartz and the cell baseline is distorted. This alteration might persist for several hours or eventually become irreversible. The adsorption of solute on the cell surfaces is often significant for biopolymer samples and requires thorough cleaning of the cells in chromosulfuric acid or for largely cationic solutions in basic solutions. Checking the pH of the solution used to wash the cell after this treatment is a surprisingly sensitive indicator of the completeness of the cleaning process.

As the ECD spectrometer operates in the single beam mode, the position and orientation of the cell during the baseline and sample scan should be identical. Dependence of the ECD spectrum shape on the distance of the cell from the photomultiplier might indicate light scattering on the aggregates of the solute. A combination of the sample concentration and the cell pathlength is used to adjust the sample absorbance to 0.6–0.8. Artifacts related to the low light intensity and high gain on the photomultiplier are observed for higher absorbances.

As the instrumentation for VCD measurements is less standardized, the experimental protocols depend on the particular spectrometer. In the FTIR instruments, the saturation of the sensitive semiconductor detectors by the high light throughput might require use of optical filters, which reduces the multiplex advantage of this technique.

The successful measurement of VCD of biological samples requires careful choice of the solvent and cell window material and the cell construction. Windows of BaF$_2$ separated by Teflon or Mylar spacers and either demountable or refillable cells have been used for protein, peptide, and nucleic acid VCD studies. Baselines for VCD measurements are generally recorded under experimental conditions identical to those of the sample with a solvent-filled cell. Alternatively, a solution of poly(L,D)-lysine with the absorbance at 1650 cm$^{-1}$ adjusted to match that of the measured sample can be used to minimize the impact of the absorption-related artifacts in protein VCD studies. Simultaneous measurements of IR absorbance of the VCD sample allow normalization of the measured VCD
spectra. Absorbance of the sample at the maximum of the corresponding IR band or the area under the absorption spectrum is used to compensate for uncertain pathlength and concentration of the protein. This method assumes that the extinction coefficients for different molecules are identical and is, therefore, only an approximation in the absolute sense.

4 STRUCTURAL INTERPRETATION OF CIRCULAR DICHROISM SPECTRA OF BIOMOLECULES

4.1 Quantitative Empirical Methods

The earlier part of this chapter has discussed structural features of biomolecules and physical mechanisms that can generate observable changes in CD spectra in all frequency regions. The inverse problem, methods to derive the maximum quantitative structural information from CD spectra, will be critically assessed using as an example the empirical methods of CD spectral analysis of proteins. Many aspects of protein spectroscopic structural studies can be generalized and applied in the investigation of other biomolecules.

The key steps of the structure encoding and decoding in CD are shown in Figure 17. The molecular structure of any molecule is transformed into a CD spectrum through its interaction with the (polarized) light in a spectrometer. Details of the molecular structure are necessarily reduced in this step to the level given by the structural sensitivity of the chiroptical technique used. Without the quantitative theoretical model, necessary structure–spectra relationships cannot be determined by the analysis of a single spectrum. Empirical methods, therefore, use series of spectra measured for a set of reference molecules with known structures (e.g. determined by X-ray crystallography). Variation of the spectral bandshape that represents various aspects of molecular structure in the set of reference experimental spectra and the known structure of the reference molecules then constitute the input to the analysis. As a direct consequence of the limited structural sensitivity of the optical spectra, numerous structural features are necessarily convoluted and unresolved in the spectral representation. The goal of an empirical analysis method is, therefore, twofold. First, the structural features that induce observable and systematic changes of the spectral bandshape should be identified in the reference set of molecular structures. Second, the variability of the reference spectra should be parsed into components that correlate significantly with the trends of structural variation identified by the previous step. This correlation should be finally described in a mathematical form that is instrumental in predicting unknown molecular structures.

Figure 17 The steps in a selective empirical analysis of the informational content in biomolecular spectra. A representative set of reference molecules with known structure are projected through the selected spectroscopic method. The interdependencies in the reference spectra are analyzed and the bandshape variability in the set is defined by quantitative descriptors. An algorithm that reduces details of the reference molecular structures to a level compatible with the structural sensitivity of the spectroscopic method and quantifies them in terms of the structural descriptor components can be derived. An optimal and selective mathematical algorithm is finally developed to predict the various aspects of molecular structure from the spectral variability in the reference spectra and multiple structural descriptors which are derived from the known molecular structure of the reference molecules that can be related to different parts of the spectral variability in the reference set.
Spectra–structure correlation is developed by relating quantitative descriptors of spectral variability to quantitative descriptors of structural variability in the reference set. These two representations of the molecular structure should have a comparable level of resolution. Cartesian coordinates of reference molecule atoms need to be transformed into quantitative structural descriptors that represent the reduction of the atomic details to the spectroscopic resolution level. One example of such structural reduction is the determination of a protein secondary structure and subsequent calculation of its SSF.\(^{(101–106)}\)

The SSF was historically considered as the only quantitative structural parameter that is extractable from ECD spectra of proteins.\(^{(107,108)}\) Recent results showed that this assumption is too restrictive: there are structural features that go beyond the SSF and can be successfully predicted from CD spectra in various regions.\(^{(107,109,112)}\) The following summary is formulated nontraditionally so that these new results can be incorporated into the general formulation of spectral analytical methods.

Any empirical interpretive method formulates a quantitative and selective (mathematical) transformation between the spectral variability and the variability of the chosen structural descriptor (Figure 17). The important first step in this formulation is to find the minimal number of independent components that are needed for a complete description of the spectral variability in the reference set. This information prevents overinterpretation of the experimental data and – more importantly – facilitates the decomposition of the experimental spectra into logical subsets, which are called spectral components, bands, or subspectra. Quantification of their contributions to the analyzed spectra is one of many ways for describing the spectral bandshapes numerically. These components can be also combined in various ways in the optimization of the correlation to structural descriptors.

Application of the same principle – determination of the number of independent components in the set of structural descriptors for the reference protein set – helps to reveal any interdependence between their values. The analysis can be simplified and additional criteria for the evaluation of the accuracy and precision of the predictions can be obtained, if any such relationship exists. The next section summarizes methods and examples suitable for such a development.

### 4.2 Analysis of the Reference Set Properties Using Principal Components

If we organize reference spectra column-wise into a matrix \([\Theta_i(\lambda)]\) with rows corresponding to frequencies or wavelengths \((\lambda)\) and columns \((i)\) attributed to the individual molecules (e.g. proteins) of the reference set, then the number of independent components in our spectral series is equal to the rank \(p\) of that matrix. Any mathematical method of rank determination can be used to find the \(p\). Principal component analysis (PCA), one of the statistical methods of variance analysis, is the standard algorithm for this purpose.\(^{(110,111)}\) This method was utilized not only for protein CD spectra analysis but also in numerous other spectroscopic applications.\(^{(112–115)}\) PCA decomposes the reference spectra set into a linear combination of \(p\) orthogonal (linearly independent) basis functions (subspectra). In the mathematical formulation of PCA, the spectral intensities of the analyzed data matrix \([\Theta_i(\lambda)]\) are considered as variance from the common (zero) mean value. PCA basis functions are defined in this variance space by the requirement that the projections of the spectral intensities into them are maximal, that the basis functions are orthogonal, and that the correlations between the experimental spectra are preserved after the decomposition. This is the optimization problem with multiple boundary conditions that can be solved using the method of Lagrange multipliers. Its solution leads to the secular equation and determination of eigenvalues and eigenvectors of the correlation or covariance matrix of the experimental spectra.

With this understanding of the underlying statistical background, further development is straightforward matrix algebra. We have a set of \(N\) linear equations that define the decomposition of any CD spectrum \(\Theta_i(\lambda)\) \((i = 1, \ldots, N)\) from the reference set into the linear combination of \(p\) common independent subspectra \(\phi_j(\lambda)\) \((j = 1, \ldots, p)\):\n
\[
\Theta_i(\lambda) = \sum_{j=1}^{p} C_{ij} \phi_j(\lambda)
\]  

To define the spectral correlation matrix that is needed for PCA algorithm, Equation (13) can be rewritten as

\[
\Theta_i(\lambda) = A_i \sum_{j=1}^{p} C_{ij} \phi_j(\lambda)
\]

where

\[
A_i = \int_{\lambda_1}^{\lambda_2} \Theta_i^2(\lambda) \, d\lambda
\]

is the normalization constant corresponding to the area of each decomposed spectrum.

The correlation matrix \([R]\) of the experimental spectra that is needed to solve the secular problem defined above can be calculated as

\[
[R] = [w_i(\lambda)]^T [w_j(\lambda)]
\]
where
\[ w_i(\lambda) = \frac{1}{A_i} \Theta_i(\lambda) = \sum_{j=1}^{p} c_{ij} \phi_j(\lambda) \]  
(17)
and T is the transpose operator. The elements \( r_{ij} \) of the correlation matrix \([R]\) are, in fact, the numerically calculated values of the overlap integrals for all spectral pairs in the reference set:
\[ r_{ij} = \frac{\lambda_2}{\lambda_1} w_i(\lambda) w_j(\lambda) \, d\lambda \]  
(18)
Any numerical algorithm can be substituted for the simplest method determining this integral using Equation (16). Principal components of the correlation matrix \([R]\) are, in fact, the numerically calculated values of the overlap integrals for all spectral pairs in the reference set:

\[ r_{ij} = \frac{\lambda_2}{\lambda_1} w_i(\lambda) w_j(\lambda) \, d\lambda \]  
(18)

The series of Equations (13–19) mathematically transform \([\Theta_i(\lambda)]\) into the diagonal matrix of eigenvalues \([\Lambda_j \delta_{ij}]\). It is known that these operations preserve the rank \( p \) of the analyzed set of CD spectra, which is thus defined as the number of nonzero eigenvalues in \([\Lambda_j \delta_{ij}]\). Such a simple result can be obtained only for ideal data without noise. All eigenvalues are nonzero for real spectra with noise, and \( p \) is then defined as the minimal number of subspectra needed to reconstruct experimental spectra using Equation (14). Numerous criteria can be used for the determination of \( p \). An excellent analysis of this problem studying the impact of experimental noise on the results of PCA is available.\(^{116}\)

For spectroscopic applications, it is practical to calculate the differences between the experimental and reconstructed spectra for a gradually increasing number of subspectra. Ordering of the subspectra according to their importance for the description of the reference set spectral features is needed for that purpose. Such an ordering is possible using the fact that according to the PCA statistical model the calculated eigenvalues are proportional to the fraction of the total variance accounted for by the associated basis function. Individual basis functions can be sorted according to their significance for the description of the spectral variability in the decomposed set using the eigenvalues associated with them. The minimal number of subspectra for which the differences between the experimental and the reference set spectra, reconstructed from the subspectra ordered according to their eigenvalues, do not exhibit significant spectral features then defines the value of \( p \).

Once we know how to decompose the reference spectra set into the principal components, it is equally important to recognize any correlations or dependencies between the reference set structural descriptors or their components. This knowledge might contribute significantly to the method design and simplification. We can organize the structural descriptors of the reference molecules into matrix \([D_i(k)]\), which is constructed from \( k \) rows corresponding to individual descriptor elements (e.g. fractions of helix, sheet, etc.) in \( N \) columns representing the reference set molecules. This matrix can be subjected to the rank analysis as described above. The extent of the relation between the elements of three descriptors of protein structure is discussed below in the light of the rank analysis as an illustrative example.

We chose a representative set of protein structures from the protein data bank that spans all structural types. This set corresponded to 430 structures with good data quality and less than 25% sequence identity.\(^{116}\) There are three types of structural descriptor that have been used until now for CD spectroscopic structural studies of proteins: SSF, fractions of distorted secondary structures,\(^{109}\) and matrix descriptors for secondary structure segments determination.\(^{69,70,117}\) Construction of these descriptors requires the secondary structure assignment of each amino acid residue that was found using the algorithm for the determination of the secondary structure of proteins.\(^{101}\) Figure 18 summarizes the protocol for derivation of the last two descriptors from the secondary structure information. The elements of these descriptors were organized into matrices with 430 rows and corresponding numbers of columns for all proteins (five for SSF, including helix, sheet, turn, bend, and other; three for fractions of distorted secondary structures that included helix, sheet, and other; and nine for matrix descriptors of secondary structure segments, which were \(3 \times 3\) matrices as shown in Figure 18).
CIRCULAR DICHROISM IN ANALYSIS OF BIOMOLECULES

Secondary structure fractions

SSF$_\alpha$ = 100(10 + 15)/80 = 31.50%  SSF$_\beta$ = 100(8 + 10)/80 = 22.50%  SSF$_\gamma$ = 46.25%

Fractions of distorted secondary structure

Distort$_\alpha$ = 100(2 + 2 + 2 + 2)/80 = 10.00%  Distort$_\beta$ = 100(1 + 1 + 1 + 1)/80 = 5.00%

Figure 18 The derivation of descriptors related to the number of secondary structure segments in the protein fold. After the secondary structure assignment, the linear segment model is constructed (rectangles, $\alpha$-helix; arrows, $\beta$-strands; lines, loops; numbers above the segments are the lengths of the segments in the amino acid residues; shaded rectangles and numbers inside the segments are the number of residues assumed to be distorted by the segment end-effects). SSFs and distorted SSFs are calculated as shown in the top part of the figure. The linear segment code is then generated (C, H, and E are “central” unperturbed parts of loop, helix, and strand segments, respectively; ch, hc, ce, ec, eh, and he are respective segment boundaries) and the numbers of all segment and boundary types are organized in the matrix scheme shown at the bottom.

protein folds. Figures 19–22 demonstrate graphically the extent of the descriptor element interdependencies that is the reason for the calculated result. It is clear from Figure 19(a) that for the SSF descriptor the dominating interdependence exists between helix and sheet fractions. This was also shown earlier by the neural network study.$^{118}$ This interdependency is generally overlooked, although it is not very surprising. It reflects the fact that most globular proteins are typically composed of about 70% ordered structure (helix and $\beta$-strands). Proteins made of turns and disordered structure are rare and, consequently, the fractions of bends and turns in the studied set do not exhibit such interdependence. This, in turn, results in projection of the helix–sheet correlation into their relations with “other” fractions (see Figure 19b). This is demonstrated for a typical content of ordered structures in a globular protein by the linearity of the helix–strand fraction dependence, with the average line cutting the fractional content $\alpha$ and fractional content $\beta$ axes at 70.

Fractions of distorted secondary structures are significantly dependent on the total corresponding SSF values, as is seen in Figure 20(a) and (b). Correlation is stronger for strand than for helical segments. The helix–sheet interdependence discussed above is, therefore, projected also into significant correlation between fractions of distorted helices and strands (Figure 20c). Elements of matrix descriptor for determination of secondary structure segments are much less significantly related to the corresponding SSF values than is the previous descriptor (Figure 21). They also exhibit (with the exception of relations between numbers of strand and other segments) a lesser degree of interdependence, demonstrated in Figure 22.
Figure 19 Interrelation of the SSF values for helix, sheet, and “other” in globular proteins. (a) Correlation of the sheet to helix SSFs in the set of 430 representative protein structures selected from a protein data bank and processed by the determination of the secondary structure of proteins algorithm for secondary structure assignment of helices, sheets, bends, turns, and “other”. (b) Correlation of fractions of helix, sheet, and other structures, demonstrating the minimal impact of the bend and turn fractions on the observed statistical dependency.

Figure 20 Interrelations of the distorted SSF values of helix and sheet segments in globular proteins. Fractions of secondary structures considered to be distorted can be correlated with the corresponding total SSF values found by the determination of the secondary structure of proteins algorithm for secondary structure assignment of helices, sheets, bends, turns, and “other”: (a) helix–distorted helix; (b) sheet–distorted sheet. (c) Interrelation between the fractions of distorted sheet and distorted helix in the representative set of 430 protein data bank structures.

Figure 21 Interrelation of the number of helical and sheet segments to the fractions of helix and sheet in globular proteins. The number of (a) helical and (b) sheet segments (elements H and E of the matrix descriptor in Figure 18, respectively) are correlated with the helical and sheet SSFs for the representative set of 430 protein data bank structures.
4.3 Analysis of the Compatibility of the Analyzed Elements

Define similar practical error limits for other descriptor elements (Figures 19–22) can be used to determine the sheet fraction from CD spectra of that descriptor. For example, the absolute error in the number of helical, sheet, and "loop" segments in globular proteins. The number of helix segments (elements H, E, and C of the matrix descriptor in Figure 18, respectively) are correlated for the representative set of 430 protein data bank structures.

Figure 22 Interrelation of the number of helical, sheet, and "loop" segments in globular proteins. The number of helical–sheet, helical–loop, and sheet–loop segments (elements H, E, and C of the matrix descriptor in Figure 18, respectively) are correlated for the representative set of 430 protein data bank structures.

As a practical consequence of these approximate dependences, any empirical method of structural analysis of protein spectra should be able to predict multiple components of protein structural descriptors with errors smaller than the variance of the relations between these components. If this is not the case, it cannot be unambiguously determined if protein spectra really contain information about more than one component of that descriptor. For example, the absolute error in determination of the sheet fraction from CD spectra should be significantly smaller than 15%. Envelopes of the correlation plots (Figures 19–22) can be used to define similar practical error limits for other descriptor elements.

4.3 Analysis of the Compatibility of the Analyzed Protein Spectrum and the Reference Set

Before applying any empirical algorithm extracting structural information from the experimental CD spectrum of a sample with unknown structure, it is necessary to ensure that the analyzed spectrum is compatible with the reference spectra. Practically, such a testing can be based upon an algorithmized concept of similarity between the unknown and the reference spectra because the measured spectra are usually the only information available about the analyzed sample. Any quantitative pattern recognition or statistical method can be used for this purpose. The following examples are selected to demonstrate various strategies of compatibility testing.

One possibility is to calculate the correlation coefficients ("overlap integrals") \( r_{\text{Unknown}, \text{ref}} \) of the studied CD spectrum \( \Theta_{\text{Unknown}}(\lambda) \) with all other spectra \( \Theta_{\text{ref}}(\lambda) \) in the reference set after normalization as (Equation 23):

\[
r_{\text{Unknown}, \text{ref}} = \frac{\lambda_{2}}{\lambda_{1}} \int_{\lambda_{1}}^{\lambda_{2}} w_{\text{Unknown}}(\lambda) w_{\text{ref}}(\lambda) \, d\lambda
\]

The unknown spectrum should exhibit statistically significant correlation to several or all reference CD spectra.

Because the problem has multiple dimensionality, cluster analysis is another algorithm that can be used for confirmation of compatibility of the analyzed and reference spectra. Clustering might be performed directly with the spectra (see Figure 23a) or using the principal component loadings \( C_{ij} \) or \( c_{ij} \) (see Equations 13 and 22). The last technique is more sensitive to unique features in the analyzed spectrum because principal component decomposition generates extra subspectra for features that are uncorrelated to spectral variance of other samples. High loadings of this extra subspectrum for the spectrum that contains this unique feature then discriminate clearly the outlier by its large generalized distance from the rest of the proteins in the reference set (Figure 23b).

Neural networks \( ^{119} \) can be also used to confirm the compatibility of analyzed and reference spectra. For this effect, the autoassociative network is trained to project spectra of the reference data set into themselves. \( ^{120} \) The general topology of such a projection neural network is shown in Figure 24(a). The network has \( n \) input and \( n \) output neurons, each corresponding to one wavelength of the spectra. During the training process, these neurons are filled with the respective intensities at the corresponding wavelengths. The network is trained (backpropagation is a suitable paradigm for this purpose) by optimization of synaptic weights matrices \( w_{A} \) and \( w_{B} \) that transmit the spectra through the potentials of a selected number of hidden-layer neurons. The number of neurons in the hidden layer can be optimized. This process should balance the number of degrees of freedom in the data used to train the network and its capability to generalize, i.e. to interpret new spectra. This is equivalent to finding a relation between the number of hidden neurons and the complexity of the analyzed data. The PCA of the weights exported from the pre-trained network with a
Figure 23 Comparison of the cluster analysis of 28 protein ECD spectra using direct and principal component representation of their bandshape. (a) Dendrogram characterizing the similarity in the reference set. Clustering was calculated with the 200 equidistantly digitized ECD intensities as input and with the Lance–Williams flexible clustering algorithm. (b) Lance–Williams flexible clustering of the reference protein ECD spectra using the loadings of the five principal components needed to decompose the spectra as in Equation (13). ALB, albumin; MYO, myoglobin; HEM, hemoglobin; LDH, lactate dehydrogenase; TIM, triose phosphate isomerase; LYS, lysozyme; CYT, cytochrome c; LCF, lactoferrin; RHD, rhodanese; THA, thaumatin; ADH, alcohol dehydrogenase; THE, theromylsin; CON, concanavalin A; CAH, carbonic anhydrase; REI, immunoglobulin; PAP, papain; RNA, ribonuclease A; RNS, ribonuclease S; GRS, glutathione reductase; SBT, subtilisin bpn; LCG, lactoglobulin; SOD, superoxide dismutase; CGN, chymotrypsinogen; CAS, α-casein; CHT, chymotrypsin; ELA, elastase; PTI, trypsin inhibitor; TRP, trypsin.

large number of hidden neurons (~60 for about 100 input spectral intensities) can be used for this purpose in the special case of spectra analysis. The method is able to find the rank $p$ of the weight matrix, and the optimal network topology will, therefore, have $p$ hidden-layer neurons.

The hidden layer actually decomposes the processed spectra into components that are in many aspects similar to subspectra discussed in the previous section. Equation (24) defines the actual calculation that the trained backpropagation neural network performs during the projection of the spectra $\Theta(\lambda)$. (The hyperbolic tangent is used as the transition function that determines the “firing” of each neuron and weight matrices $w_A$ and $w_B$ were obtained by training.)

$$\Theta(\lambda) = \tanh((w_B)^T \tanh((w_A)^T \Theta(\lambda))) \quad (24)$$

If we substitute $\psi$ for $\tanh((w_A)^T \Theta(\lambda))$ and invert the tanh function, we can demonstrate the formal analogy of the network action with the PCA decomposition (Equation 14).

$$\arctanh(\Theta(\lambda)) = (w_B)^T _\psi \approx \Theta(\lambda) + \frac{\Theta^3(\lambda)}{3} + \frac{\Theta^5(\lambda)}{5} + \cdots \quad (25)$$

Equation (24) shows explicitly the nonlinear character of the network processing of the spectra. If only the first term of the expansion is preserved, then a matrix of weights $(w_B)^T$ would play the role of the subspectra and the hidden neuron potentials $\psi$. 
Figure 24 Reduction of protein VCD spectra into synaptic weight components of the autoassociative projection neural network. (a) The topology is shown of the autoassociative backpropagation neural network after optimization for projection of VCD spectra of 28 proteins through the single hidden layer using as input 100 equidistantly recorded VCD intensities. The desired output and the number of hidden layer neurons were optimized to four as described in the text. (b) A spectral representation of the network synaptic weights connecting the respective hidden layer neurons \(V_1 - V_4\) to the output layer is given. As the output intensity is the sum of hidden layer potentials scaled by these weights, the picture demonstrates the decomposition of the experimental VCD spectra into network-generated component spectra (subspectra).

would correspond to a column of the coefficient matrix in Equation (22). Figure 24(b) demonstrates that this algebraic analysis corresponds to the actual network behavior. The connection weights between the hidden layer and output neurons in the autoassociative networks trained to project protein VCD spectra on themselves are plotted as a function of frequency. These plots of network weights can be definitely interpreted as the spectral components.

The spectrum of the unknown protein is submitted as input to the trained neural network with an optimized topology and its projected reconstruction is compared with the experimental prototype. If there are no significant differences, the spectrum of the analyzed protein can be considered to be compatible with the training set reference information.

4.4 Description of the Spectral Variance

The next step in the analysis is to describe quantitatively the variability of the bandshape of reference and analyzed spectra (Figure 17). There are numerous methods for encoding the shape of a spectrum into numbers that can be used as the input information for an algorithm correlating them to structural descriptors. These methods range from determination of the intensity at a selected wavelength to neural network algorithms.

1. The single wavelength intensity method. The molar ellipticity of the negative maximum at 222 or 208 nm is determined from protein ECD spectra.\(^{107,108}\)

2. The similarity method. The correlation coefficient (overlap integral) of all spectra in the analyzed set with one reference spectrum is determined.
using Equation (23). In this method, the spectral bandshape is represented by a single number with magnitude between $-1.0$ and $1.0$ that characterizes the similarity or dissimilarity of each spectrum to the reference one.

3. Cluster analysis method. Intensities at regularly spaced frequency intervals of the spectrum are determined; the shape is represented “as is” in the form of a single vector of equidistantly spaced spectral intensities.

4. Band deconvolution method. The CD spectra are broken down into a series of $p$ common component bands so the bandshape of any spectrum is encoded in a vector with $3p$ parameters defined by position, half-width, and amplitude of each component band.

5. Methods using component spectra. These approaches deconvolute the spectra into a series of $p$ component spectra. These spectral components might have different origins, which define the principal difference between various interpretive methods that utilize such spectral bandshape encoding. They might be derived from CD of model compounds (peptide ECD were used to decompose protein ECD); they might be represented by spectra of reference molecules with known structure, or by the basis functions (subspectra) defined mathematically using PCA, singular value decomposition, or neural networks. In all these methods, the bandshape of any spectrum is quantified by a set of $p$ vectors with dimension identical to the number of points in the analyzed spectrum and one $p$-dimensional vector of the component spectra loadings (e.g. $p$ subspectra $\phi_i(\lambda)$ with a row of coefficients $C_{ij}$ in Equation (13) or matrix of weights and hidden-layer neuron potentials in analogy to Equation (25).}

6. Neural network methods. These processing programs map spectra–structure relations using optimization of neuron potentials and synaptic weighting.

To further emphasize the bandshape variability, it might be advantageous to transform the reference and processed spectra into the difference variant by subtracting the set-average spectrum from them. It should be noted that the quantitative bandshape variability decomposition with mathematically defined component spectra could be performed independently on the structural part of the problem. This is equivalent to analysis recognizing the internal correlations between the various spectral features, which can be then used with advantage in comparisons with the available structural information.

4.5 Description of the Spectra–Structure Relation

There is a validation protocol that is used almost universally to assess the degree of success during development of an empirical technique for biomolecular spectral analysis. It is called “one-out testing” and will be explained first. Its implementation requires that the spectral bandshape decomposition is already established together with the algorithm that projects the spectral components into the structural descriptor values. For “one-out testing”, a new reference set of spectra and structural descriptors are created from the original ones by eliminating the spectrum and the structural descriptor of one reference molecule. This reduced set is used to optimize the projection function parameters in the spectra–structure relation. The left-out spectrum is then processed by the re-optimized relation as if it is an unknown sample. Structural descriptor predictions are compared with the known values for the “one-out” reference molecule and the prediction error is stored. This procedure is repeated by eliminating systematically all reference spectra and the corresponding descriptors one by one. A series of prediction errors is thus collected. The standard deviation $\sigma_i$ is calculated from them as a quantitative characterization of the method prediction error. Alternatively, relative standard deviations, $\sigma_{i,rel}$, can be used because their values are less dependent upon differences in the reference sets. They are calculated from the standard deviation $\sigma_i$ of “one-out” prediction of structural type $i$, and the dynamic range of the structural descriptor values in the reference set, $d_{i,max}$ and $d_{i,min}$ (Equation 26):

$$\sigma_{i,rel} = \frac{\sigma_i}{d_{i,max} - d_{i,min}} \times 100\% \quad (26)$$

The next step in the development of the analysis method is to establish a relationship between spectral bandshape descriptors that were determined by the methods summarized above and the molecular structure descriptors of the reference molecules (Figure 17). Two complementary strategies can be applied. First, it can be assumed that all spectral components are related exclusively to the variability of the structural descriptor. A typical example of this approach is the assumption that the changes in ECD spectra of proteins have to be exclusively related to the variation in SSF. The second type of strategy postulates that only a subset of the spectral variability components can be related to the information encoded by the molecular structure reduction into the structural descriptor values (Figure 17).

The two strategies also employ different mathematical tools for establishing quantitative spectra–structure relations. In the first category, a dominant role is played by algebraic and optimization tools that are designed
to convert all spectral components and their numerical loadings into the descriptor values. They are based on the following set of assumptions.\(^{113}\)

- Every studied CD spectrum is completely explained as a linear combination of component spectra. In the case of protein ECD, these component spectra characterize individual secondary structures. There is no spectral demonstration of the effect of the tertiary structure in this case.
- There are no differences between the averaged structures of the molecules studied in solution and in crystalline form (studied by spectroscopy and X-ray diffraction, respectively).
- Spectral contributions from chromophores or physical mechanisms that uniquely modify the spectral bandshape but are not universal for all processed spectra do not alter the analysis results. In the case of protein ECD spectra, this is equivalent to the assumption that contributions from nonpeptide chromophores (e.g. the aromatic side chains) are negligible.
- Structural types used to formulate the quantitative structural descriptor are characterized as rigid, ideal (secondary) structures. For proteins, this assumption is equivalent to neglecting the variability of ideal helical or sheet dihedral angles.

Mathematical algorithms for the second analysis strategy must contain some information filter that optimally selects the subset of all spectral components in the reference set and differentiates them from components that are unrelated to the question defined by the predicted structural descriptor. Examples of such algorithms are the variable selection method,\(^{103,104,106,128–131}\) ridge regression algorithms,\(^{124}\) complete multiple linear regression optimization,\(^{66,101,109,112,117,125,136,138}\) and response analysis of the trained neural network.\(^{69,70,132–135}\) Various mathematical methods have been used to relate the structural descriptors of proteins to the spectral bandshape characteristics (1–5 above); these are now described in more detail as a practical example of this stage in the methodology.

4.5.1 Single Wavelength Intensity Method

The simplest relations that are useful for rapid monitoring of protein conformational changes are the linear correlations between the ellipticity at 222 or 208 nm in a protein ECD spectrum and the fraction of \(\alpha\)-helix.\(^{110,111}\) The errors in the absolute predictions of helical fractions from these values are only moderately less accurate than those from more sophisticated methods. The reason for the success of this method is that the \(\alpha\)-helical spectral bandshape dominates ECD once the protein contains 25% or more helical structure. Therefore, the intensity at a single wavelength is a good descriptor of the overall spectral bandshape. The disadvantage of this method is its limitation to prediction of only one secondary structure and its sensitivity to contributions from other chromophores if they contribute to the ECD intensity at the selected wavelength.

4.5.2 Similarity Method

The similarity method still relies on a single number that characterizes the spectral bandshape but utilizes all measured spectral points for that characterization. It was developed\(^{121}\) to analyze the protein VCD in the amide III region (1100–1400 cm\(^{-1}\)). This approach is based on the evaluation of similarities of the spectral bandshapes between the reference and analyzed VCD spectra that are quantified by the value \(r_{ij}\) of overlap integrals between them (Equation 23). These \(r_{ij}\) values are calculated numerically by interpolating the product of the two spectra by natural cubic spline functions and integrating the result. Linear regression is then used to relate the \(r_{ij}\) values to reference protein SSFs. There is an optimization step involved in the determination of the final regression function \(SSF_{k,i} = k_{ref,i} + q\). There is no a priori indication as to which protein spectrum should be selected as the reference bandshape. Therefore, all possibilities should be tested systematically by selecting all protein spectra in the set as the reference bandshape. These tests should be performed independently for all secondary structure types and the linear equation with the lowest prediction error in “one-out testing” should be used for the processing of the VCD spectra of the unknown samples. This method is suitable for structural studies that use spectra with unavoidably large intensity errors. Overlap integrals \(r_{ij}\) are calculated from the spectra \(w_i(\lambda) = \Theta_i(\lambda)/A_i\) normalized by the spectrum area \(A_i\) defined by Equation (15). Intensity variations are thus removed from \(r_{ij}\) and only the bandshape is involved in the similarity quantification. A disadvantage of the method is the lack of flexibility in the selection of the function representing the spectra–structure relation, which can have only one independent variable.

4.5.3 Cluster Analysis Methods

Spectral bandshape “as is” can be understood as a multicomponent vector characterizing the protein structure. In this model, every one of the \(n\) measured frequencies represents one dimension of a generalized \(n\)-dimensional space. The CD intensity at that frequency stands for a coordinate that defines the unique protein position in that space. Cluster analysis algorithms provide measures for distance determination in such multidimensional
A generalized distance matrix can be determined in the CD spectra space by the application of these algorithms to the spectral matrix $[\Theta_i(\lambda)]$ (see section 4.3). Graphical representation of the generalized distance matrix, usually in the form of a dendrogram, is then used to visualize the results. The distances are ordered hierarchically and connected in a dendrogram scheme that uses the calculated relative similarity indices for all proteins (see Figure 23a).

Unsupervised clustering constitutes usually the first step in the pattern recognition or discrimination analysis. In an unsupervised clustering, the structural interpretation of the resulting dendrogram can be found by comparison with another clustering of the reference protein set that is based on the structural descriptors as generalized protein coordinates. Ideally, both spectrally based and structurally based clusters of the proteins in the reference set should be organized into similar hierarchical schemes. Selection of the various metrics and algorithms for cluster definition can be used to optimize this spectra–structure dendrogram similarity. This methodology was applied to protein ECD and VCD spectra characterization in terms of SSF values. Characterization of protein tertiary structure folding class (all-$\alpha$, all-$\beta$, all-$\alpha$/$\beta$, $\alpha+\beta$, and denatured proteins) using clustering of their ECD spectra was implemented.

In a supervised clustering, parameters of the generalized distance can be adjusted using the protein structural feature under investigation so that the resulting clusters are forced to reflect both the spectral and structural similarity. Both the applications mentioned above found that clustering similar to that based on the complete CD spectra can be obtained when only three to five principal component loadings $C_{ij}$ of the experimental spectrum decomposition by PCA algorithm are used as the protein coordinates (see Equations 18 and 12). One study used this simplification of the protein spectral coordinates to define a decision function optimized to discriminate between the known tertiary structural classes of the reference protein set. This function has the same number of parameters, $W_i$, $i = 1, \ldots, N$, as the number of data points in the processed spectrum. These parameters are found in the perceptron algorithm training that uses the spectra and the known fold types in the reference set. Assignment of the structural class for an unknown protein is based on the value of scalar product $D$ between its spectrum $\Theta_i(\lambda)$ and parameter vector $\overrightarrow{W}$ (Equation 27):

$$D = \overrightarrow{W} \Theta_i(\lambda) = \sum_{i=1}^{N} W_i \Theta_i(\lambda) + W_0 \quad (27)$$

Clustering algorithms are suitable for studies of structural features that are difficult to encode quantitatively. Protein tertiary structure class characterization is an example of such a fuzzy structural concept. The user needs to handle the multiplicity of metrics for generalized distance calculations and multiplicity of clustering algorithms that can generate very different similarity schemes with the same inputs. Application of several algorithms and retaining only those clusters that are identified invariantly in all or most of the calculations might be tedious but it is a relatively robust strategy to avoid overinterpretation of a specific clustering.

4.5.4 Band Deconvolution Methods

Deconvolution of the CD spectra into component bands became useful for protein structural studies only with the advent of VCD. Frequency sensitivity of the IR bands is much greater than that of electronic transitions, especially in the amide I vibration region at 1550–1750 cm$^{-1}$, which is dominated by the carbonyl stretch mode. Unfortunately, the bisignate character of the CD spectrum increases deconvolution ambiguity, as is demonstrated in Figure 25. Two deconvolutions of the albumin VCD spectrum implements different numbers of peaks but are...
indistinguishable on the level of standard deconvolution error criteria. To retain acceptable and consistent solutions for all proteins in the set, a multistep procedure had to be applied in the deconvolution of the spectra of the 23-member protein VCD set that generated the example. Simultaneous processing of IR absorption spectra of the same proteins after their FT self-deconvolution and second-derivative calculation were used in the process. Multiple optimization cycles with selective band parameter restrictions were necessary. Despite this effort, component peak areas were uncorrelated to SSF values. The main contribution of VCD spectroscopy to the structural interpretation of protein vibrational spectra is the unambiguous proof that secondary structural assignments of various amide I component bands are, indeed, ambiguous. Amide I component bands with the same characteristic frequencies but opposite signs of CD components were clearly identified in the FTIR and VCD spectra of many proteins. This is a semiquantitative argument but its strength stems from the structural requirements that are necessary to change the VCD band sign. The bands with the opposite VCD signs cannot arise from the same type of structural elements even though the frequencies appear from FTIR measurement to be the same.

4.5.5 Methods with the Component Spectra

Methods that deconvolve reference set CD spectra into a linear combination of the component spectra (subspectra) use the most informative transformation of the experimental input. The independent or selective treatment of various spectral features becomes possible only at this level of spectral variability description. This transformation of the experimental spectra also facilitates testing of the multiple combinations of the component spectra against various protein structural features in the final relationship optimization. There are several conceptual differences characterizing algorithms that can be classified using the criteria listed in Table 2.

There are several ECD analysis methods that use subspectra of various origins with invariant shape for the unknown spectrum decomposition but no selection of spectral features or modification of the reference set is then performed.

4.5.5.1 Methods Using Experimental Circular Dichroism Spectra of Synthetic Polypeptides or Reference Proteins

Multiple linear regression was used in classical methods to express the experimental CD by a linear combination of model peptide subspectra. These algorithms exist in variants with and without consideration of non-negativity and constraining the sum of predicted SSF to 100%. SSFs of α-helix, parallel and antiparallel β-sheet, turn, and “other” conformations can be determined with good relative prediction errors. In a further development, the subspectra derived from a reference protein ECD set that generated the example [107,108] used in classical methods to express the experimental CD by a linear combination of model peptide subspectra. These algorithms exist in variants with and without consideration of non-negativity and constraining the sum of predicted SSF to 100%. SSFs of α-helix, parallel and antiparallel β-sheet, turn, and “other” conformations can be determined with

Utilization of subspectra

\( \phi_j(\lambda) \) or coefficients \( C_{ij} \) as the bandshape descriptors

Variable selection of proteins in the reference set

Variable selection of subspectra and their combinations

Variable selection of the spectral frequency region that is used for processing

Variable generation of multiple spectra–structure relationships optimized to predict structures of various reference proteins and use of similarity descriptors to find the relationship optimized for reference protein with the closest spectral bandshape to that of the unknown

The subspectral description is the unambiguous proof that secondary structural elements are present. This method is characterized by the use of similarity descriptors to find the closest spectral bandshape to that of the unknown protein CD spectra analysis in terms of SSFs. The SSF prediction is then optimized by selective statistical weighting of contributions of reference ECD spectra to the spectra–structure relation.
4.5.5.2 Methods Using Mathematically Derived Component Circular Dichroism Spectra

The next group of methods uses subspectra derived by a purely mathematical transformation of reference CD spectra. The convex constraint method uses simplex optimization to find related intensity changes and groups them into subspectra that are then attributed to some secondary structural type according to the calculated bandshape. It is allowed that one secondary structure can be characterized by more than one convex constraint subspectrum. Most other algorithms from this group are based on subspectra generated by projection of the reference spectra to an orthogonal basis using eigenvectors of correlation or covariance matrix (see section 4.3)\(^{(133)}\).

Singular value decomposition, variable selection method, self-consistent method, and restricted multiple linear regression implement various combinations of the features summarized in Table 2. All have been applied to protein ECD spectra to predict SSFs; only restricted multiple linear regression has been used for protein VCD spectra analysis. The self-consistent method is the only one from this group that was used for prediction of a structural descriptor other than SSF. All but restricted multiple linear regression use subspectra to find the structural descriptor. The major differences between these methods are the optimization principles on which they are based. All but restricted multiple linear regression solve a so-called generalized inverse equation that generates subspectra from matrices of structural descriptors and experimental CD spectra of the reference set. The unknown protein spectrum is then expressed as a linear combination of these subspectra with coefficients providing the structural fractions. In this sense, the methods follow the conventional model of decomposition of the experimental spectrum into secondary structure-related subspectra. These spectral components are the best least-squares approximation of the spectral response to fractions of various secondary structures in the reference set.

**Differences of Individual Algorithms.** In the singular value decomposition and variable selection method, the unknown spectrum is not processed with the reference set. To optimize the prediction performance, the program systematically selects various subsets of reference spectra and repeats the prediction cycle with monitoring of boundary conditions for the SSF. Acceptable solutions are averaged.

In the self-consistent method, the unknown spectrum is processed together with the reference spectra. This co-processing cannot be completed without the values of the unknown SSF. The method overcomes this difficulty by similarity-based initial guessing of the unknown SSF and iterative process. The subspectra determined by the modified variable selection method of singular value decomposition of the whole set are used to determine the first iteration of the unknown protein SSF. This result is substituted for the initial guess; a new set of subspectra is determined and the process is repeated until the SSF for the unknown protein does not change in consecutive cycles.

**Using the Spectral Component Loadings Instead of the Subspectra.** Restricted multiple linear regression uses a completely different approach. The first step is principal component decomposition (Equation 14) of the reference spectra together with one or more spectra of unknown proteins, which is mathematically exact and does not require any initial estimates or iterations. Calculated subspectra are used only as basis functions that provide coefficients \(C_{ij}\), which characterize numerically the bandshape variability of both reference and unknown spectra for each analysis. This step is again exact, without any fitting or additional optimization. The number of these coefficients, which is initially equal to the number of processed spectra \(N\), is reduced to a minimal number \(p\) necessary to reproduce the experimental bandshapes: typically from \(N \approx 30\) to \(p \approx 5–10\). To test the quality of the reconstruction, the difference between the experimental and reconstructed spectra is calculated and the differentials are monitored. The final set of \(N \times p\) numbers (loadings in the factor analysis nomenclature) represents the pool of digitally encoded spectral components that are assumed to be dependent on various aspects of protein structure, not exclusively on the SSF.

The next step – restricted multiple linear regression – optimizes the combination of these components into a subset that best predicts the selected structural descriptor, SSF. The optimal restricted multiple linear regression relationship for each possible total number, \(n\), of component loadings \(C_{ij}\), \(n = 1\) to \(p\), is sought in the regression cycle in which all possible combinations of \(n\)-tuples generated from \(p\) loadings are used. Each combination of loadings in the given pool defines a different linear multivariate function, which is then tested for its accuracy as a descriptor of the correlation between \(C_{ij}\) and SSF values by the one-out testing. In this step, five to eight best models that yielded minimal prediction error and an optimal multivariate regression coefficient in fitting are found from the complete tested set and saved. These prediction errors for all stored models are then plotted against the number \(n\) of loadings \(C_{ij}\) or \(c_{ij}\) in the multiple linear regression models. The model with the best prediction standard deviation is used for the final processing of all proteins, including the unknown. If spectral representation is needed, selected optimal regression model parameters are used as coefficients in the linear combination of the subspectra selected in the optimization step to predict a
given secondary structural type. The advantage of this method is that there is no additional approximation in the decomposition of the unknown spectra. It is also possible to process more than one unknown spectrum simultaneously. The algorithm is fast and allows for optimizations including the complete search for combinations of as many as 16 subspectral coefficients in reasonable time. For this size of the pool, 65,535 regression calculations are solved. The method explicitly assumes that the subspectra needed for the experimental CD spectra reconstruction are not all related to SSFs. Figure 26 graphically represents the results of component selection in the analysis of protein ECD and VCD spectra. Optimal prediction of all SSFs from ECD spectra requires a model with only one coefficient related to the most significant subspectrum. A model with four subspectral coefficients optimally predicts the protein helical and strand SSFs from VCD spectra. In both cases, the one-out method of testing proved that the incorporation of additional loadings into the models actually deteriorates the prediction error.

4.5.6 Neural Network Methods

Neural network algorithms are processing programs that create spectra–structure mapping by optimization of neuron potentials and weights of synapses between the
calculational nodes (neurons). The backpropagation and Kohonen self-organization map in conjunction with the prediction network are paradigms used to process the protein CD spectra.\textsuperscript{(132,134,143)} Although the details of the decomposition of experimental spectra into subspectra are less transparent than in the above methods, subspectra can be represented either by the exported values of synaptic weight (as discussed in section 4.3) or by the interchange of input and output. The network can be trained to recognize spectra from the structural descriptor values. The subspectra related to particular structural types can be predicted by submitting a descriptor of pure conformation (e.g. 100% helical protein) to the trained network. The spectrum of the unknown protein cannot be processed together with the reference set. The method does not use any constraints on calculated descriptor values. Spectroscopic interpretation of the network mapping mathematics is similar to that described in section 4.3.

In all neural network methods for prediction of SSFs from the ECD spectra, the frequency interval used for analysis can be selected.\textsuperscript{(144)} Another neural network backpropagation scheme has been used to predict elements of matrix descriptor for protein secondary structure segments (section 4.3).\textsuperscript{(69)} This approach is an alternative to determining the number of secondary structure segments using the self-consistent method optimized to predict fractions of distorted secondary structure (Figure 18). Optimal performance is achieved when the unknown protein CD spectrum is first assigned to a subcategory of the reference set proteins. This assignment is based on clustering of the analyzed spectrum with those from the reference set proteins by using the SSF composition of the unknown protein that was previously determined from its spectrum. The improved prediction performance is achieved by using a re-trained network that minimizes the prediction error for protein with the CD spectrum most similar to the unknown one. The matrix descriptor provides in the diagonal elements equivalent structural information to that of the self-consistent method; the off-diagonal elements are information that is additional and complementary. The advantage of this descriptor is in its independence of the number of amino acid residues considered as distorted.

\[ \Theta_i (\nu) = \sum_j C_{ij} \delta_j (\nu) \]

\[ FC_i = c_0 + K_{i1}C_{i1} + K_{i2}C_{i5} + K_{i3}C_{i6} \]
5 QUANTITATIVE RELATION OF CIRCULAR DICHROISM SPECTRAL INFORMATION TO OTHER SPECTROSCOPIC TECHNIQUES

5.1 Two-dimensional Correlation Analysis of Series of Circular Dichroism Spectra

The general features of the established two-dimensional correlation method were used for a comparative analysis of independent sets of protein optical spectra with respect to an “internal” structural perturbation.\(^\text{145-147}\) The method used the fractional compositions of three major protein secondary structure types as the perturbation for obtaining heterospectral correlation maps for ECD, FTIR, and Raman spectra of the same set of proteins. The approach used a polynomial fit to the intensity variance at each frequency to generate the heterospectral correlation two-dimensional maps. This method generates an arbitrary number of points in the second dimension that represents the averaged response of the spectra to secondary structure variation in the set proteins. It emphasizes any correlations that arise while effectively eliminating or minimizing any asynchronous responses by appropriate rearrangement of the analyzed spectra. The algorithm improved the spectral resolution and generated new assignment of the spectral regions, which were mutually correlated through the protein structural feature used as a perturbation. The method is applicable for any spectroscopic study that results in statically measured reference sets of spectra that vary with respect to some other physical parameter, such as higher-level structure or even a biomedical diagnostic variable. An example of the heterospectral two-dimensional synchronous correlation map that uses variation of ECD spectral intensities and signs to identify bands in protein Raman spectra with different responses to the variation of helical and sheet SSF is shown in Figure 27.

5.2 Neural Network Projections Between Circular Dichroism and Other Methods

The degree of interconvertibility of VCD spectra of proteins into ECD has been studied using heteroassociative rather than autoassociative neural networks.\(^\text{123}\) In the calculation, the input layer neurons were loaded with either ECD or VCD normalized equidistant intensities. The network topology was then optimized in a two-step training procedure to predict the spectral bandshape of the protein spectrum measured by the complementary method. The optimal number of hidden layer neurons was determined by PCA of the exported weights, and by analysis of the network response to input variations. The results demonstrated that the two spectroscopic methods are not fully independent. Not all spectral features of VCD spectra were predictable from their ECD counterparts. The higher variability of the VCD bandshape, which stems from it being a vibrational mode with intrinsically higher-resolution components, leads to the higher sensitivity of VCD to structural variation. Similar studies of VCD spectra measured in D\(_2\)O and H\(_2\)O do not show the trends that occur in the ECD/VCD mapping and, therefore, confirm that measurement of vibrational spectra in either solution yielded equivalent structural sensitivities.

Figure 27 Two-dimensional heterocorrelation between the protein ECD and Raman spectral changes related to the variation of the helical SSF in the reference set. Positive (a) and negative (b) parts of the two-dimensional synchronous heterocorrelation map between protein ECD and Raman spectra calculated with respect to the change of helix fraction as the internal spectral perturbation. Extrema of these correlations indicate the Raman bands that are dependent on the helical content in the protein structure.
6 CONCLUSIONS

The presented discussion shows that CD spectroscopy is not only a technique for the analysis of secondary structure of proteins (as is the common perception of this method) but also a valuable spectroscopic tool for analytical applications. It encompasses multiple aspects of biomolecular properties, which can be studied through their interaction with CPL. With the new developments in instrumental, theoretical, and interpretive applications of the chiroptical methods, CD spectroscopy remains an invaluable tool in any bioanalytical study.

Fluorescence-based Biosensors

John D. Brennan
McMaster University, Hamilton, Canada

1 INTRODUCTION

In the past two decades, there has been explosive growth in the development and application of fluorescence-based biosensors. Such devices generally use a biological reagent, such as a protein or nucleic acid strand, to derive a selective interaction with an analyte of interest. To obtain a fluorescence signal, the analyte may be inherently fluorescent, may undergo a reaction, such as an enzyme-catalyzed hydrolysis, that leads to fluorescent products, or may compete with a fluorescently tagged analog for binding sites on a protein. Alternatively, the biological reagent may itself be fluorescently labeled. In this case, interactions between the analyte and biomolecule can produce fluorescence signals owing to alterations in the biomolecule structure or dynamics.

Fluorescence-based biosensors may utilize emission intensity, emission wavelength, fluorescence anisotropy or fluorescence lifetime measurements. Such signals may arise from selective perturbations that change the concentration of a fluorescent species, or those that alter polarity, pH, charge or viscosity, thereby changing the emission properties of the fluorophore. A detailed description of fluorescence principles and applications is given by Lakowicz, while the theoretical basis of various fluorescence-based signals used for biosensors has been presented in detail by Lubbers.

The remainder of this chapter begins with a brief outline of the history of optical sensors. This is followed by a description of some key aspects of sensor development, including instrument design, and a brief review of the methods used to interface biomolecules to optical devices. The fluorescence assay techniques associated with different types of biomolecules and the applications of various fluorescence-based biosensors are then described, with particular emphasis on areas where such sensors are

scattering systems such as milk or whole blood, or relatively inaccessible locations such as groundwater wells, or even intracellular environments.

The key limitation of such devices mainly centers around the poor stability of biological compounds, which can lead to a substantial drift in instrument response over time. There is also the potential for interferences related to biological autofluorescence, and the analyte-dependent sensitivity and limit of detection (LOD) for sensors, which rely on the nature of both the protein and the fluorescent probe utilized. Finally, in cases where immunological reagents are used, the devices can show a lack of reversibility, and may operate only as a "one-shot" screen, without the potential for continuous, quantitative analysis.

1 INTRODUCTION

In the past two decades, there has been explosive growth in the development and application of fluorescence-based biosensors. Such devices generally use a biological reagent, such as a protein or nucleic acid strand, to derive a selective interaction with an analyte of interest. To obtain a fluorescence signal, the analyte may be inherently fluorescent, may undergo a reaction, such as an enzyme-catalyzed hydrolysis, that leads to fluorescent products, or may compete with a fluorescently tagged analog for binding sites on a protein. Alternatively, the biological reagent may itself be fluorescently labeled. In this case, interactions between the analyte and biomolecule can produce fluorescence signals owing to alterations in the biomolecule structure or dynamics.

Fluorescence-based biosensors may utilize emission intensity, emission wavelength, fluorescence anisotropy or fluorescence lifetime measurements. Such signals may arise from selective perturbations that change the concentration of a fluorescent species, or those that alter polarity, pH, charge or viscosity, thereby changing the emission properties of the fluorophore. A detailed description of fluorescence principles and applications is given by Lakowicz, while the theoretical basis of various fluorescence-based signals used for biosensors has been presented in detail by Lubbers.

The remainder of this chapter begins with a brief outline of the history of optical sensors. This is followed by a description of some key aspects of sensor development, including instrument design, and a brief review of the methods used to interface biomolecules to optical devices. The fluorescence assay techniques associated with different types of biomolecules and the applications of various fluorescence-based biosensors are then described, with particular emphasis on areas where such sensors are

scattering systems such as milk or whole blood, or relatively inaccessible locations such as groundwater wells, or even intracellular environments.

The key limitation of such devices mainly centers around the poor stability of biological compounds, which can lead to a substantial drift in instrument response over time. There is also the potential for interferences related to biological autofluorescence, and the analyte-dependent sensitivity and limit of detection (LOD) for sensors, which rely on the nature of both the protein and the fluorescent probe utilized. Finally, in cases where immunological reagents are used, the devices can show a lack of reversibility, and may operate only as a "one-shot" screen, without the potential for continuous, quantitative analysis.
uniquely suited. Finally, a comparison with other methods and future prospects for these devices are presented.

2 HISTORY

Fluorescence emission has been known since the turn of the century, and much of the theoretical basis of the process was described in the first half of this century. In the 1950s, commercial fluorescence instrumentation became available, and this led to numerous studies of biological systems and the development of several fluorescence-based biological assays.\(^{(21)}\) In the early 1970s, Harrick reported the first use of total internal reflection fluorescence (TIRF) to measure the emission of dansyl-labeled bovine serum albumin (BSA) adsorbed onto a quartz waveguide.\(^{(22)}\) Shortly thereafter, Kronic and Little\(^{(23)}\) reported the first application of TIRF to immunosensing, wherein the interaction between a fluorescein-labeled antibody and a surface-immobilized hapten were quantitated. This work ushered in the modern era of fluorescence-based biosensing.

Over the years, numerous fluorescence-based biological assays have been adapted to a configuration suitable for sensing applications. Initially, biological reagents such as antibodies, enzymes, and membrane-bound receptors were used for sensor development,\(^{(24)}\) since these species were available in high purity, or could be extracted from living tissue. More recently, species such as regulatory proteins,\(^{(25)}\) RNA,\(^{(26)}\) DNA\(^{(27)}\) and nucleic acid aptamers\(^{(28)}\) have been exploited for optical sensor development. In these cases, the development of new optical biosensors had to wait for advances in molecular biology and for the emergence of new synthetic tools, such as solid-phase synthesis of DNA, before the biomolecules could be obtained. At present, increased collaboration between sensors specialists (mainly chemists, physicists and engineers) and biomolecule specialists (biochemists and molecular biologists) is leading to a new era in sensor development, wherein biomolecules are being designed to have intrinsic signaling capabilities, engineered immobilization regions, or enhanced thermal stability. Aspects of these advances, and how they are extending the range of applications for such devices, are discussed below.

3 INSTRUMENTATION

Numerous instruments have been utilized for fluorescence-based biosensors, and it is not possible to describe all of the various configurations here. The majority of instrumentation used for fluorescence-based biosensors is based on optical fibers or planar waveguides. Figure 1 shows some of the typical instrumental configurations for fiber-optic sensors. Such devices consist of an excitation source, a beamsplitter to separate excitation and emission radiation, the fiber or waveguide with the immobilized biomolecule, and a detector and readout to process the signal. Typical sources include Xe lamps and a variety of lasers. More recently, light-emitting diodes (LEDs) have been used owing to their small size, low cost and useful spectroscopic characteristics, with some LEDs now emitting in the near UV region, where numerous probes absorb. Beamsplitters, as shown in Figure 1, generally consist of either a bifurcated optical fiber, a dichroic mirror, which separates light on the basis of wavelength, or a perforated mirror, which is generally used with collimated sources such as lasers. Detection of emitted radiation is usually done with a photomultiplier tube. However, recently developed sensors now utilize miniature detectors, including photodiodes, diode arrays, or charge-coupled device (CCD) cameras (for imaging of sensor arrays).
The optical fiber or waveguide is the heart of the fluorescence-based biosensor. Optical fibers provide a compact and rugged sensing device, and allow for remote spectroscopic measurements. A detailed description of the physical processes involved in transmission of light through an optical fiber is given elsewhere\(^{(9)}\). The properties of optical fibers which must be considered for sensor device development have been reviewed by Seitz\(^{(29)}\) while the principles of planar waveguides have been reviewed by Dessy\(^{(30)}\). The key aspect that makes these components of use for sensor development is their ability to propagate light via the process of TIR. TIR occurs when a ray of light that is propagating through a transparent medium of high refractive index encounters an interface with a medium of lower refractive index at an angle of incidence that is greater than a critical angle, which is given by the inverse sine of the ratio of external over internal refractive indices.

A consequence of the TIR process is that an evanescent field arises at the reflection points in the waveguide, and has the same wavelength characteristics as the waveguided radiation. The evanescent field intensity decays exponentially with distance into the less dense medium, with typical penetration depths being on the order of one-half of the wavelength of the guided radiation, or about 200–400 nm for visible radiation. In fabricating a fiber-optic chemical sensor the sample region is usually placed onto the surface of the waveguide in the form of a thin film, which interacts with the excitation radiation through the evanescent field. The short penetration depth of the exciting radiation results in preferential excitation of surface-bound species, and reduces interferences from bulk solution.

### 4 INTERFACING OF BIOMOLECULES TO DEVICES

To develop self-contained biosensors using biological components such as proteins or nucleic acids, the biorecognition element and, ideally, the fluorescent reporter group, must be put into intimate contact with a physicochemical transducer to allow excitation of fluorescence and detection of emission from the biorecognition element. For proteins, typical immobilization strategies have included physical adsorption of the protein onto the surface of a waveguide, various covalent immobilization strategies, and entrapment of the protein either within a semipermeable membrane or into an organic or inorganic polymer matrix\(^{(31)}\). For nucleic acids, single strands of DNA or RNA can either be grown onto surfaces one base at a time using solid-phase synthesis methods\(^{(27)}\) or intact strands can be immobilized either through interaction of biotinylated DNA with avidin-coated surfaces\(^{(32)}\), or by direct covalent attachment of the nucleic acid strands to a suitable surface\(^{(33)}\). The latter methods are preferred owing to difficulties associated with the solid-phase synthesis methods, including the likelihood of incomplete strand formation, and the problems with protecting group chemistry, which make it difficult to retain DNA on surfaces during deprotection of some bases.

Protein immobilization has been widely studied, and numerous reviews exist outlining the advantages and disadvantages of the various immobilization methods. Early examples of sensors utilizing TIRF were based on proteins that were adsorbed to surfaces\(^{(14)}\). However, while adsorption is a straightforward method for immobilization of biomolecules, many biomolecules adsorb in inactive orientations, or undergo irreversible denaturation upon adsorption to an inorganic surface\(^{(34)}\). Desorption of proteins subsequent to immobilization on a surface is also a problem. The constantly changing nature of the selective surface leads to an inability to maintain calibration of the sensing device.

A more common strategy for immobilization of a biomolecule is covalent linkage onto reactive sites on the surface of the transducer. The activating agents available for covalently linking a protein to a hydroxylated surface have been thoroughly reviewed by Weetall\(^{(35)}\). The functional groups on proteins that are suitable for binding to activated surfaces have been discussed by Srere and Uyeda\(^{(36)}\). Recent progress on protein immobilization has focused on methods for controlling the orientation of the immobilized biomolecule. Three approaches are commonly used for this purpose. The first is the use of a Protein A underlayer on a surface to aid in the immobilization of intact antibodies, which will bind through the complement region, resulting in the antigen binding regions facing toward the solution\(^{(37)}\). A second method is to place a streptavidin layer onto the surface, and to then bind selectively biotinylated proteins onto the surface to achieve orientational control. For example, Piervincenzi et al.\(^{(38)}\) have demonstrated that single chains comprising the variable region of the antigen binding fragment (scFv) can be site-selectively modified with a peptide which a high affinity for streptavidin. This allowed immobilization of the scFv onto a streptavidin coated surface with a high degree of orientational control. A final method involves derivatizing the surface with a thiol-reactive species, and then reacting with a specific cysteine (Cys) within the protein. This method has been widely used for oriented immobilization of Fab fragments of antibodies\(^{(39)}\).

The other major method for interfacing biomolecules to optical surfaces is by entrapment in a polymeric matrix. Typical organic matrices include nylon and

---

polyacrylamide.\(^{40}\) In this case, the protein is not physically bonded to the surface, and orientation is not an issue. The porosity of the matrix is such that small molecules can enter, while the larger biomolecules remain entrapped. While organic materials have been relatively successful for entrapment of proteins, the reaction conditions employed are often harsh, and can result in substantial loss of biomolecule function.

An emerging method for protein immobilization is entrapment of biological components into inorganic silicate matrixes formed by a low-temperature sol–gel processing method.\(^{41,42}\) The hydrated glass (sometimes referred to as a bioglass or biogel) contains a significant amount of entrapped water, and as a result, the biologically doped glasses maintain the activity of entrapped compounds, such as enzymes and antibodies, over periods of several months. A major advantage of these materials is that they are optically transparent, making them ideal for the development of chemical and biochemical sensors that rely on changes in a fluorescence signal.\(^{43}\) Interested readers are referred to the reviews by Avnir et al.\(^{41}\) and Dave et al.\(^{42}\) for specific details pertaining to entrapment of biomolecules by this method.

### 5 APPLICATIONS OF FLUORESCENCE-BASED BIOSENSORS

The applications for which fluorescence-based biosensors may be used are numerous, and are limited only by the ability to develop a fluorescence-based assay that is sensitive to the presence of a desired analyte. Applications can be classified into those that are qualitative, simply involving the identification of a compound, and those that are quantitative, providing data about the concentration of a given analyte in a sample. Examples of qualitative applications include the use of biosensors as chromatographic detectors,\(^6\) use of DNA arrays (gene chips) for the identification of genetic materials,\(^44\) and the use of beads containing fluorescently tagged proteins for high-throughput drug screening.\(^5\) While these are important applications for fluorescence-based biosensors, owing to space limitations this chapter will focus solely on those applications that are able to provide quantitative information about analyte concentrations.

#### 5.1 Applications of Protein Engineering to Sensor Design

The ability to develop a biosensor for a specific analyte has generally been determined by the availability of purified biomolecules. At present, a wide variety of enzymes and antibodies are commercially available, and development of antibodies against specific analytes is fairly routine. However, even though such species are available, there are still a large number of analytes for which no biomolecules are available, and there is also a need to improve the currently available arsenal of selective proteins. The three main areas where protein engineering can aid in sensor development are:

1. selective placement of fluorescent labels into biomolecules to form reagentless sensors;
2. placement of reactive groups within the biomolecule to allow oriented attachment to surfaces;
3. engineering of thermostable proteins to help overcome difficulties associated with a loss of protein function over time.

In the first case, proteins can be prepared containing a single tryptophan (Trp) residue that is sensitive to analyte binding,\(^{45}\) or a single reactive Cys residue which can be reacted with a thiol-selective fluorescent probe to provide an analyte-dependent reporter group.\(^{46}\) Numerous examples of such proteins exist,\(^{47}\) and reports are now appearing describing their use for sensor development.\(^{48}\) The engineering of proteins containing reactive Cys residues is also useful for obtaining a selective site for attachment of proteins to derivatized surfaces.\(^{49}\) It is also possible to selectively biotinylate a protein to control the orientation of binding to a streptavidin-coated surface, as described in section 4.\(^{50}\) The final area of protein engineering, which is only now beginning to be explored, is the mutation of proteins to enhance their thermal stability. There are recent reports showing dramatic stabilization of protein structure and function as a result of a single residue mutation.\(^{51}\) Such proteins are likely to be exploited for development of sensors with improved long-term stability.

#### 5.2 Enzyme-based Sensors

Enzyme-based sensors have been developed using a variety of different signal transduction methods, including amperometric, potentiometric, absorbance and fluorescence approaches. Fluorescence-based enzyme sensors have been utilized for a variety of applications, as outlined in Table 1. These include biomedical monitoring (i.e. glucose and urea), monitoring of agents of environmental and defense interest (mainly enzyme inhibitors), and detection of heavy metals, which are often required cofactors for enzyme activity. The advantages of fluorescence-based detection strategies include freedom from electrical interferences, reduction of interferences related to matrix components with half-cell potentials similar to that of the reaction of interest.
(a good example is ascorbate interferences in electrochemical glucose sensing), and the ability to monitor reactions involving species that are not electrochemically active. Disadvantages include background signals from inherently fluorescent biological components, and high background signals when sensing in opaque or highly scattering media.

Many enzyme-based fluorosensors have relied on the detection of a fluorescent signal change arising from the consumption of a fluorescent analyte, the production of a fluorescent product, or the change in signal from a secondary fluorescent reporter due to product formation.\(^{(51)}\) In such cases, one can use the Michaelis–Menten equations to determine analyte concentration from the initial rate of reaction, provided that the Michaelis constant \(K_m\) for the enzyme is known under the conditions of use. Examples of this approach include a variety of sensors for ethanol, urea, ACh, glucose, lactate, glutamate, cholesterol, penicillin, and other species. In most cases, transduction occurs either by monitoring a change in pH using a pH-sensitive dye (ACh, urea, penicillin\(^{(50)}\)), \(O_2\) concentration via quenching of a stable fluorescent dye such as the tris(4,7-diphenyl-1,10-phenanthroline) ruthenium(II) complex (glucose,\(^{(55)}\) cholesterol,\(^{(56)}\) lactate\(^{(57)}\) and others), or changes in NADH fluorescence (glutamate,\(^{(58)}\) ethanol,\(^{(59)}\) pyruvate\(^{(59)}\)). More recently, enzyme-based fluorosensors have used for pesticide detection. For example, organophosphorus hydrolase (OPH) was used for reagentless fluorimetric determination of nine different organophosphates.\(^{(60)}\) In this case, FITC was covalently bound to the enzyme to detect product dependent changes in pH in the local vicinity of the enzyme. In the case of paraoxon, the dynamic range extended from 25 to 400 μM with a detection limit of 8 μM.

An extension of the above approach is to monitor the concentration of enzyme inhibitors, which can be easily quantitated using the standard equations describing the effect of inhibitor concentration on reaction rates. Such sensors are particularly useful for detection of compounds of environmental or defense interest, since many such compounds act as enzyme inhibitors. A recent example of such a sensor is the use of sol–gel immobilized cholinesterase for detection of organophosphorous pesticides, which act as inhibitors of the enzyme.\(^{(61)}\) Substances such as mercaban could be analyzed at levels ranging from 5 to 330 μg mL\(^{-1}\) in under 5 min. While such schemes are feasible, they rely on the presence of both the substrate (or a fluorogenic analog) and the analyte, and hence are not amenable to reagentless sensing.

Several reagentless enzyme-based sensors have also been developed utilizing the fluorescence of bound cofactors, such as FAD, for signal development.\(^{(62)}\) A recent example is the use of changes in FAD fluorescence from sol–gel entrapped redox enzymes to detect glucose, cholesterol or L-amino acids.\(^{(63)}\) The signal was based on the reduction of FAD to FADH\(_2\), which produces a reversible change in the intensity of emission that is proportional to analyte concentration. Using this approach,
sensing of glucose or cholesterol could be done over a millimolar concentration range, which corresponds to the lower range of physiological interest for these species.

A promising alternative route to obtain a reagentless enzyme-based sensor is to use a fluorescent inhibitor that binds to the protein only in the presence of a specific cofactor. Thompson and Jones initially demonstrated this approach for sensing Zn(II), based on the binding of a dansylamide inhibitor to the Zn(II) cofactor after the cofactor had bound to the active site of carbonic anhydrase. Initial studies used the inhibitor in solution and utilized fiber-optic detection. In this case, the concentration of metal ion over the range of 50 to 1000 nM was found to be proportional to the ratio of fluorescence intensities at two emission wavelengths, corresponding to emission from the bound and free inhibitor.

More recent work from Thompson et al. has focused on the use of fluorescently labeled carbonic anhydrase for detection of picomolar to nanomolar levels of Zn(II), Co(II) and Cu(II) utilizing fluorescence anisotropy, and for monitoring of picomolar concentrations of Cu(II) and Zn(II), and nanomolar concentrations of Cd(II), Co(II), and Ni(II) using fluorescence lifetime data as an analytical signal. In both cases, a fluorescent sulfonylamine probe was bound to a single Cys residue that was placed near the enzyme active site via site-directed mutagenesis, making the sensor reagentless. This work represents one of the most sensitive methods for detection of heavy metals, and in some cases exceeds the detection limits of standard methods, such as atomic emission techniques using inductively coupled plasma sources.

### 5.3 Fluoroimmunosensors

Immunosensors comprise the largest single class of biosensors, and a wide variety of transduction methods have been reported for such sensors, including those based on surface plasmon resonance (SPR), electrochemical, absorbance and fluorescence strategies. Numerous examples of such sensors exist, and interested readers are referred to reviews on immunosensor properties and applications that have appeared in recent years. Most work in the area of fluoroimmunosensors has centered on three common approaches, as outlined in Figure 2. The first is direct detection of fluorescent analytes. The second is the competitive assay format, wherein the analyte (which may be either an antibody or a hapten) competes with a known concentration of a fluorescently labeled analog for binding sites on a surface. The third common method is the sandwich assay format, wherein a large antigen with multiple antibody binding regions is first bound to a primary antibody present on a surface, and is then complexed with a second, fluorescently labeled antibody to derive a signal.

As shown in Table 2, fluoroimmunosensors have been used for analytes of biomedical, defense and environmental interest. Most examples involve detection of proteins or small analytes. However, immunosensors have also been used to detect very large analytes, such as viruses and other pathogenic organisms.

Examples of immunosensors which utilize the intrinsic fluorescence of the analyte are not widespread; however, they are used in the specific area of PAH detection. As an example, Alaire et al. described a fiber-optic immunosensor for benzo[a]pyrene which relied on the direct detection of the bound analyte using evanescent excitation. In this case, a LOD of 20 nM and a dynamic range of spanning three orders of magnitude could be obtained with an equilibration time of 20 min, although a washing step was required to remove unbound analyte. In such cases, bound analyte can often be discriminated from free analyte using fluorescence polarization measurements, thereby removing the need for a washing step and improving response times.

Many more immunosensors utilize competitive immunoassay methods, particularly for smaller analytes.

IgG, immunoglobulin G; HSA, Human serum albumin; PAH, polyaromatic hydrocarbon; TNT, 2,4,6-trinitrotoluene; Cyt, cytochrome; FRET, fluorescence resonance energy transfer; TRITC, tetramethylrhodamine-5-isothiocyanate; NDV, Newcastle disease virus.

Examples of biomedical immunosensors utilizing the competitive assay format include one for the detection of human IgG using a planar waveguide,\(^71\) and a series of sensors for the detection of cocaine,\(^72,73\) all being based on displacement of a labeled analog from an immobilized antibody. In the latter case, cocaine could be detected directly in leaf extracts, with results that were in good agreement with those obtained using gas chromatography (GC). A drawback of this approach was that the sensor provided stable responses for only 14 days.

Competitive fluoroimmunosensors are also widely used for compounds of environmental and defense interest. For example, a competitive immunoassay for trinitrotoluene was reported, which had a LOD of 10 ng mL⁻¹ using a 5 min equilibration time.\(^74\) Astles and Miller\(^75\) reported a phenytoin fiber-optic immunosensor utilizing an energy transfer-based signal. In this case, an antibody labeled with Texas red (acceptor) was mixed with B-phycoerythrin-labeled phenytoin (donor), and interaction of these species caused quenching of the phycoerythrin signal. Increased binding of free phenytoin resulted in a shift in antibody binding equilibria between labeled and unlabeled phenytoin, producing a proportional increase in fluorescence. Using this system, phenytoin could be detected over a dynamic range of 250 µM with a LOD of ~1 µM. An identical system was also described for detection of free theophylline, and gave similar analytical results.\(^76\)

Competitive\(^77,78\) assay methods have been used for the detection of pathogenic organisms of interest in both the food and defense industries. An example of a competitive assay involved the binding of botulinum toxin B to immobilized antitoxin B IgG. This reaction competed with the binding of biotinylated toxin. Higher levels of the analyte resulted in lower levels of bound the biotinylated analog, resulting in a lower fluorescence signal upon addition of FITC-labeled streptavidin.\(^77\)

Examples of sandwich assays are also numerous. A key advantage of sandwich-based immunosensors is that they
are useful for larger species such as viruses and pathogenic organisms, which generally express antigenic proteins within their coat membranes. For example, a sandwich assay was used for the detection of Clostridium botulinum toxin A. Toxin A antibodies were covalently bound to a quartz optical fiber and incubated in solutions of toxin A and a TRITC labeled antitoxin A antibody. The fluorescence signal was directly proportional to the amount of toxin A present, and a detection limit of 5 ng mL\(^{-1}\) was achieved with a response time of 10 min.\(^{(78)}\) Similar strategies have been utilized to detect the F1 surface antigen of Yersinia pestis.\(^{(79)}\) The protective protein, PA, which is co-expressed with the anthrax toxins,\(^{(80)}\) and protein A, which is a product secreted by Staphylococcus aureus,\(^{(81)}\) in the first two cases, polyclonal or monoclonal antibodies were attached to the surface of a tapered optical fiber to capture the antigen, and TRITC-labeled monoclonal anti-F1 or anti-PA IgG was used for signal generation. In each case, an LOD of 5 ng mL\(^{-1}\) was reported using a 30 min incubation time, and the dynamic range extended to 100 ng mL\(^{-1}\) of antigen. In the latter case, antiprotein A was adsorbed to a plastic optical fiber, and was used to capture protein A. FITC-labeled antibody was then added to generate a signal. Using this approach, a LOD of 1 ng mL\(^{-1}\) was reported. A final example of the utility of the sandwich assay approach is the detection of the potently toxic protein ricin by a sandwich immunosensor.\(^{(82)}\) An antiricin IgG was immobilized onto the surface of an optical fiber, and the binding of ricin was quantitated using a fluorescently tagged secondary antiricin antibody. The linear dynamic range of detection for ricin in buffer, using an avidin–biotin method for primary antibody immobilization, was 100 pg mL\(^{-1}\) to 250 ng mL\(^{-1}\). The LOD for ricin in river water was slightly worse, at 1 ng mL\(^{-1}\).

Detection of whole viruses has also been reported using fluoroimmunosensors. A fluorimetric sandwich assay for NDV was developed by Lee and Thompson\(^{(83)}\) based on evanescent measurements using a fiber-optic probe within a flow cell. Anti-NDV antibody was immobilized onto the fiber, and was used to capture antigen. FITC-labeled anti-NDV antibody was then made to flow past the surface and bound to captured antigen. The LOD for this method was 5 ng mL\(^{-1}\).

Immunosensors based on competitive or sandwich assay formats have enjoyed widespread use, primarily because they are amenable to a very large number of analytes, and are capable of detecting both small analytes (generally via competitive assay) and large biomolecules (using either competitive or sandwich techniques). However, as indicated above, such devices often provide slow response times, offer a limited dynamic range, show poor long-term stability, and can be tedious to use, owing to the need for washing steps. In some cases, TIRF has been used to discriminate between bound and unbound fluorescent species, and this has sometimes provided improved response times and a reduction in background interferences. Regardless of these successes, the need to add extra reagents, such as labeled analytes or antibodies, in order to quantitate analyte concentration is a serious problem for sensor development. In fact, a brief survey of the recent literature (1994 to 1999) has shown a steady decline in the number of reports describing fluoroimmunosensors, and a significant increase in immunosensors based on signals that do not require a secondary reagent for signal development. Such methods include SPR, piezoelectric and amperometric signal transduction methods.

A step toward a reagentless immunosensor has been the use of a fluorescence capillary fill device, shown in Figure 3, to introduce samples to a planar waveguide device. In this case, the antibody is bound to one face of a planar waveguide, and is used to capture analyte. All other necessary reagents, including fluorescently labeled antigens which compete with the analyte, are dosed within a thin polymer film that is on a parallel plate about 100 μm away from the immunosurface. A controlled volume of the sample is introduced by capillary action, and the presence of the buffer causes the doped film to release the reagents so that they are able to compete with the analyte for sites in the immunosurface.\(^{(84)}\) Using such a device, species such as serum rubella antibody,\(^{(85)}\) human chorionic gonadotropin\(^{(86)}\) and prostate-specific antigen\(^{(87)}\) have been detected, even in whole blood, with LODs ranging from 1.1 × 10\(^{-9}\) to 3.3 × 10\(^{-12}\) M.

Another advancement in fluoroimmunosensor design, also aimed at the development of reagentless sensor technology, has been the coupling of the analytical reporter group (i.e. fluorescent probe) directly to the immobilized antibody. In such a case, the selective binding of antigens or hapitens to the sensor surface results in a direct change in the properties of the reporter group, without the need for the addition of any extra compounds. Such a design is reagentless, since the only species that needs to be present to produce a change in a signal is the analyte itself.

One of the first developments for reagentless immunosensor design was described by Bright et al. in 1990.\(^{(39)}\) In this work, anti-HSA was incubated with HSA to block the active site of the antibody. The complex was then nonselectively reacted with dansylamine to block a solvent-sensitive fluorophore near the active site of the antibody. Removal of HSA was then carried out and the labeled antibody was immobilized near the distal tip of an optical fiber. The binding of HSA resulted in a large blue shift in the dansyl emission wavelength and an increase in emission intensity that was directly related to HSA concentration. The sensor could be regenerated
using a cheotropic solution and reused up to six times before significant changes in the fluorescence response were observed.

The use of labeled antibodies has continued to evolve in recent years. For example, myoglobin has been detected in a reagentless format using the anti-myoglobin antibody, which was labeled with the fluorescent dye cascade blue. The labeled antibody was placed into a polyacrylamide gel layer at the distal tip of an optical fiber. Binding of myoglobin resulted in FRET from the cascade blue label to the heme group of the myoglobin. Using this approach, myoglobin could be measured in a reagentless fashion with a LOD of 83 ng mL\(^{-1}\), and with a response time between 15 and 130 min.

Another exciting development which is likely to have an impact on the development of reagentless immunosensors is the use of protein engineering methods to prepare single-chain antibodies. For example, Stewart et al. have developed an intrinsically fluorescent single chain antibody, which was used to generate a reagentless fluorescence response that was related to the binding of micromolar concentrations of Zn(II). The advantage of this scheme is that the fluorophore can be placed into a location that is highly sensitive to analyte binding, resulting in the ability to tailor the sensitivity of the device.

5.4 Regulatory Proteins

One of the recent advances in the field of biosensor design, which directly addresses the issue of reagentless fluorescence-based sensing, has been the use of engineered fluorescent peptides and regulatory proteins as selective recognition elements. In most cases, these proteins are site-selectively labeled with an environmentally sensitive fluorescent probe, or are linked to a green fluorescent protein (GFP) to form a chimera. Binding of the analyte results in a direct signal via specific interactions with the probe, or an indirect signal wherein a conformational change in the protein alters the environment of the probe or GFP, producing a measurable change in the fluorescence properties (intensity, FRET efficiency, emission wavelength or anisotropy). These biorecognition elements are attractive for sensor development since in many cases they bind analytes reversibly, and have binding constants which permit detection of analytes over a concentration range spanning picomolar up to micromolar or even millimolar levels.

While many of these biorecognition elements have not yet been placed onto transducers such as optical fibers and planar waveguides, they represent an important emerging class of biomolecules that are likely to revolutionize fluorescence-based biosensors. A key advantage of such

proteins is that they can be microinjected into cells to allow studies of intracellular events via changes in fluorescence responses. Many of the applications of these biomolecules would not be possible using other techniques, and hence it is valuable to briefly review the utility of these systems here.

A number of fluorescence-based biosensors have been developed which rely on either a direct or indirect alteration in the environment surrounding the probe upon binding of analyte, as outlined in Table 3. Examples of sensors utilizing direct interactions between the analyte and protein include the use of a fluorescently labeled fatty-acid binding protein for detection of fatty acids, the use of a labeled myosin light chain to examine myosin phosphorylation events intracellularly, and the use of Cyt-c immobilized at the end of an optical fiber for fluorimetric detection of nitric oxide. In the latter case, binding of NO to the pentacoordinate Fe site in Cyt-c resulted in a change in quenching of fluorescence from the porphyrin group. Alternatively, Cyt-c could be non-selectively labeled with a fluorescein derivative whose emission overlapped the absorbance band of the porphyrin so that the label acted as a donor while the heme group acted as an acceptor for FRET. The labeled protein showed a similar sensitivity for detection of NO as the unlabeled protein, but had a substantially improved LOD, which was determined to be 20 μM. An interesting aspect of this work was that the detection of NO was done with protein that was trapped in a polyacrylamide gel at the end of a nano-optrode, measuring only 200 nm in diameter at the tip, making it possible to do measurements in volumes as small as 10 pL.

![Figure 4 Examples of protein conformational motions involving (a) shear and (b) hinge movements. The binding of the ligand results in a change in the location and hence environment of the attached fluorescent probe, producing a signal. (Adapted from Brennan.)](image)

Indirect sensors utilize fluorescently labeled proteins that undergo conformational changes on binding with analyte, resulting in a change in the environment of the attached probe, as shown in Figure 4. A wide variety of such proteins exist, and these display selectivity for a wide array of analytically interesting compounds. Examples of such proteins (with ligands in parentheses) include: citrate synthase (oxaloacetate), hexokinase (glucose), alcohol dehydrogenase (ethanol), Trp repressor (Trp), the maltodextrin binding protein (maltose), the glucose/galactose binding protein (glucose), as well as proteins which bind ligands such as Cys, glutamine, Pi and vitamin B12. Other examples include CaM (Ca2+),
lactoferrin (Fe) and cAMP-dependent protein kinase. A number of these proteins, as well as a handful of peptides, have already been site-selectively labeled with fluorescent probes and used for both intracellular and in situ sensing applications, as described below.

Zn(II)-binding polypeptides (referred to as zinc finger domains) are known to undergo Zn(II)-dependent conformational changes. Walkup and Imperiali synthesized a Zn(II)-binding polypeptide with a dansyl group placed within the cluster of residues forming a Zn(II)-induced hydrophobic pocket, and the resulting peptide showed a significant fluorimetric response to Zn(II)-induced structural changes. Ratiometric analysis, using emission wavelengths at 650 nm (Zn²⁺-free) and 525 nm (Zn²⁺-loaded) showed that the response was linear over the range from 0.1 to 1 mM Zn(II), and that the response was fully reversible. Godwin and Berg reported a Zn(II)-sensing strategy based on a principle similar to that described above. In this case, the peptide was selectively labeled at one site with lissamine, and at another with fluorescein. Binding of Zn(II) resulted in a conformational change that brought the two probes into closer proximity, increasing the energy transfer efficiency from fluorescein to lissamine. The ratio of emission intensities at 521 nm and 596 nm was sensitive to Zn(II) binding in the concentration range from 0.1 to 1.0 mM.

More recent work by Walkup and Imperiali has shown that the separation of the fluorescent reporter group from the Zn(II)-binding domain provides the advantage of being able to manipulate each part independently of the other. In this work, it was demonstrated that the affinity of the metallopeptide for binding of Zn(II) could be manipulated by altering the Zn(II)-binding domain, without affecting the performance of the attached fluorophore. Using this approach, dissociation constants for binding of Zn(II) ranging from 7 pM to 65 nM were achieved.

Examples of sensors based on fluorescently labeled regulatory proteins are numerous, and have been recently reviewed. A key application is the detection of Ca²⁺, which has been done using a variety of labeled proteins, both in solution, and in cells. A few examples also exist describing the use of such proteins for the development of fiber-optic Ca²⁺ sensors. In the majority of these cases, Ca²⁺ could be detected over the range spanning 100 nM up to 10 µM, with minimal interference from Mg²⁺ at levels up to 10 mM. Ions which had similar ionic radii to Ca²⁺, particularly Cd²⁺ and Eu³⁺, did result in substantial interferences when present at levels of 500 µM. The sensor response times were on the order of 15 min, which is longer than is desirable for a working sensor.

GFP-labeled Ca²⁺-binding proteins have also been applied to sensing of intracellular Ca²⁺ levels. Examples of this strategy have recently been reviewed by Tsien and Miyawaki. A few key examples will be presented here. One example of this is the use of a GFP-labeled CaM binding domain from MLCK to detect Ca²⁺-loaded CaM in cells via an energy-transfer method. The CaM-binding domain was labeled on one end with the BGFP, which acts as a donor, and at the other end with the RGFP, which acts as an acceptor. Binding of holo-CaM caused the GFP-labeled CaM-binding domain to adopt an extended conformation, spatially separating the BGFP and RGFP labels, and decreasing the energy transfer efficiency. Using this method, it was possible either to detect Ca²⁺ by having an excess of apo-CaM available in the solution containing the fluorescent indicator protein (denoted as FIP-CaMCaM), or to detect holo-CaM directly. In another example, the C-terminus of RGFP-MLCKf-BGFP (where MLCKf is the CaM-binding fragment of MLCK) was linked to the N-terminus of CaMCN (C and N terminal regions exchanged). These chimeric proteins responded directly to changes in free intracellular Ca²⁺ concentration through a change in the energy transfer efficiency between the two forms of GFP.

Regulatory proteins have also been used to detect organic compounds. The first use of this approach was by Gilardi et al., who examined the effectiveness of a fluorescently labeled maltose binding protein (MBP) as a maltose sensor. A single Cys mutant was constructed by replacing a serine residue at position 337 (S337C), since this position was within the cleft where maltose binding occurred, and hence experienced a large environmental change on maltose binding. Attachment of thiol selective probes such as 4-[(iodoacteyloxyethyl)-N-methylamino]-7-nitrobenz-2-oxa-1,3-diazole (IANBD) or acrylodan resulted in a system that showed a substantial increase in label fluorescence upon binding of maltose (80% for Ac, 160% for IANBD). In optimal cases, maltose could be detected over a dynamic range of approximately 500 µM, with a LOD of approximately 5 µM. Response times were on the order of several hundred seconds which were independent of ligand concentration, indicating that the rate limiting step in generating a response was likely the conformational change itself. Other fluorescently labeled MBPs, such as a D95C mutant labeled with IANBD, have also been found to be sensitive to maltose binding. This particular mutant produced a 4.4-fold increase in fluorescence intensity when saturated with maltose, and could reversibly detect maltose over a range of c. 10 µM with a LOD of c. 50 nM.

Brune et al. used an engineered phosphate binding protein for the detection of P₁. In this case, a A197C mutant was prepared, and was labeled with the probe N-[2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC). The protein undergoes a 5.2-fold increase in emission intensity in the presence of...
saturating amounts of $P_i$. The new fluorescent protein biosensor was able to detect free $P_i$ over a concentration range from 0 to 0.8 molar equivalents of protein with a dissociation constant, $K_d$, of 0.3 $\mu$M. The response was very fast (under 50 ms) and was remarkably selective. The only compound that proved to be a significant interferant was sodium arsenate, which bound with a $K_d$ of 3 $\mu$M. The potential of labeled $P_i$-binding protein as an arsenate sensor remains to be explored. The rapid response of the new protein-based biosensor has permitted measurements including the release of $P_i$ during ATP hydrolysis by actomyosin subfragment 1 ATPase or myofibril ATPases and during the interaction of p21ras with the GTPase-activating proteins p120-GAP and neurofibromin. In each case, stop-flow measurements were used to follow the reactions, and showed that the fluorescently labeled $P_i$-binding protein was able to follow extremely fast processes involving $P_i$ release, which were occurring on the millisecond timescale.

The use of labeled regulatory proteins has also been applied to the development of a sensor for glucose. In this case, single Cys mutants of the glucose/galactose binding protein were prepared and labeled with polarity sensitive probe. A L255C mutant labeled with acrylodan showed a 50% decrease in intensity and a slight red-shift in the emission maximum wavelength on binding of glucose. In this case, the sensor was responsive over a range of c. 2 $\mu$M and it had a LOD approaching the low nanomolar range. Use of a H152C labeled with IANBD produced a major change in signal (fourfold) on binding of glucose, and could measure glucose up to 100 $\mu$M, making it sensitive at the lower portion of the physiologically important range of glucose concentrations.

### 5.5 Membrane-associated Proteins

Another area of increasing importance is the use of membrane-associated proteins for the development of fluorescence-based biosensors. Recent examples include the use of the acetylcholine receptor (AChR) for detection of agonists and antagonists, the use of P glycoprotein (Pgp) to detect drug compounds, and the use of the IR to detect insulin. In the case of AChR, at least three approaches have been used. In the first approach, the protein was randomly labeled with nitrobenzoxadiazole and a fluorescence signal was generated as a result of an analyte-induced conformational change within the protein. Using this approach, ACh could be detected at micromolar to millimolar levels. The second approach relied on perturbations of the surrounding membrane upon interaction of AChR with analytes. The membrane was doped with a small amount of a fluorescently labeled lipid, which responded to membrane perturbations resulting from the conformational change of the protein. This strategy was capable of detecting carbamylcholine over the range of 300 nM to 3 $\mu$M. The final approach was to use a fluorescently labeled antagonist, FITC-$\alpha$-bungarotoxin, as a labeled analog which competed with AChR-binding compounds for sites on a AChR-coated surface. The sensor utilized AChR that was adsorbed onto the surface of an optical fiber, and the sample was excited via the evanescent wave. The sensor was able to detect unlabeled $\alpha$-bungarotoxin over the concentration range spanning 1 to 1000 nM using an equilibration time of 5 min.

The detection of drug compounds was demonstrated using Pgp that was covalently labeled with 2-(4'-maleimidylanilino)naphthalene-6-sulfonic acid (MIANS) at both conserved Cys residues, one within each of the nucleotide binding domains. ATP bound directly to the labeled nucleotide binding domains of Pgp, causing the fluorescence to be quenched by up to 15% owing to a direct interaction between ATP and the bound probe. Drug compounds, including vinblastine and colchicine, bound to a second site on the protein that was spatially removed from the nucleotide binding site. Drug binding induced a conformational change that resulted in a decrease of up to 60% in the fluorescence intensity. Using this approach, drug compounds could be detected at nanomolar concentrations over a range extending up to 10 $\mu$M.

Changes in the intrinsic Trp fluorescence of the IR have been used to detect insulin based on an analyte-induced conformational change in the protein. Binding of insulin to IR caused a 35% increase in intrinsic Trp emission intensity, a slight blue-shift in the emission maximum, and an increase in the average rotational anisotropy of the protein. These spectroscopic changes were consistent with a change in the average Trp environment in which the probes became somewhat more buried into hydrophobic regions of the protein. The response was sensitive to insulin levels ranging up to 140 nM, and response times ranged from 1 to 20 min, becoming longer as the concentration of insulin decreased.

The majority of the examples cited above were not done in a sensor format, owing to the difficulty associated with immobilizing viable membrane-associated proteins on the surface of optical waveguides. However, two recent reports have appeared describing methods that may overcome this problem. In the first case, the 5-HT$_3$ serotonin receptor was expressed with a C-terminal histidine tag to allow the solubilized protein to be bound to the surface of a planar waveguide that was first derivatized with Ni(II)nitroloacetic acid. The bound receptor was shown to retain its native, membrane-bound function, and the binding of a fluorescently-labeled serotonin analog could be detected over the concentration range of $10^{-11}$ to $10^{-8}$ M using evanescently excited fluorescence. Using a competitive assay format, the
binding of nonfluorescent species, such as serotonin, could be detected over the concentration range spanning 1 to 100 nM. The key limitation of the device was the extremely long equilibration times, which often reached several hours.

A second method for immobilization of membrane-bound proteins involved placing entire biomembrane fragments onto the surface of a planar waveguide that was part of a flow-cell. The silica surface was first alkylated, and then a lipid layer was deposited by vesicle fusion. A Na,K-ATPase-rich membrane fragment, containing FITC-labeled protein, was then physisorbed onto the lipid surface. In the absence of Na+, the sensor could detect K+ over the concentration range of 10 µM to 10 mM, with response times of less than 1 min. Inclusion of Na+ removed the K+-dependent signal, showing the effect to be K+ specific.

Another recent advancement that is likely to impact the development of sensors utilizing membrane-bound receptors in demonstration that whole organisms, such as plant and animal cells, can be successfully entrapped into sol–gel derived glasses. While no reports have yet emerged describing the use of such biomaterials for fluorescence biosensor development, the ability to cast films of these materials onto planar waveguides and optical fibers is likely to result in the development of fluorosensors using entrapped cells.

5.6 DNA/RNA-based Genosensors

While proteins are by far the most widely used biomolecules for sensor development, recent years have seen a dramatic increase in the number of sensors that utilize nucleic acids to derive selective interactions with analytes. DNA- and RNA-based devices, often termed genosensors, have been widely applied to the detection and even sequencing of DNA and RNA. In these cases, single-stranded DNA (or RNA) is placed on the surface of an optical fiber or waveguide and will bind to the complement strand in solution to form a double-stranded (ds) complex (dsDNA or dsRNA). Several approaches have been used for such sensors. One approach is to use a competitive sensing format, wherein a fluorescently tagged complement strand competes with unlabeled analyte for binding to immobilized DNA. This system could detect the labeled DNA with a LOD of 2 × 10⁻¹³ M, and the unlabeled analyte at 1.1 × 10⁻⁹ M. An alternative approach is to do a sandwich assay. In this case, a nonfluorescent analyte first interacts with single-stranded DNA on a surface, forming the dsDNA. A second DNA strand, which is labeled with a fluorescent dye, is then added to the immobilized dsDNA and binds to a different complementary region of the analyte, forming a sandwich structure that can be quantitated on the basis of emission intensity. Using this approach, as little as 25 pM of H. pylori RNA could be detected in under 1 min.

A third method for deriving a fluorescence response, which does not rely on using labeled DNA, is the use of intercalating fluorescent dyes, such as ethidium bromide (EB). This probe will preferentially associate with the dsDNA, and will produce a fluorescent signal that is proportional to the amount of complementary DNA present in the sample. Piunno et al. have used this approach to quantitate the binding of dA₂₀ in solution to dT₂₀ that was prepared on a fiber surface by solid-phase synthesis, and achieved detection limits of 86 ng mL⁻¹. This approach was also used to detect the formation of triple-helical T:AT on the surface of an optical fiber.

An extension of this approach is to immobilize dsDNA and use it to detect the binding of carcinogenic species, such as decacycline and remazo brilliant blue, which intercalate into dsDNA. In this approach, analytes displace EB which is intercalated into immobilized dsDNA, and hence produce a drop in fluorescence intensity. These species could be detected over one to two decades of concentration, with detection limits ranging from 50 ng mL⁻¹ to 10 µg mL⁻¹.

Another application for nucleic acids is the selective binding of small ligands. In some cases DNA or RNA can take up specific three-dimensional structures that are capable of selectively catalyzing reactions (ribozymes, DNA catalysts), or that can reversibly bind analyte (aptamers). Thus far, no reports exist demonstrating the use of catalytic nucleic acids for sensor development. However, there are recent reports describing the use of nucleic acid aptamers for fluorescence-based sensing. In one case, high-affinity RNA was attached to an optical fiber via an avidin–biotin bridge. Binding of FITC-labeled L-adenosine could be detected using evanescent excitation. A competitive assay was done to measure unlabeled L-adenosine, and was able to detect the analyte over a concentration range spanning three decades, with a detection limit of 100 nM. Another recent example is the immobilization of fluorescently labeled DNA aptamers directly onto a surface to allow reagentless sensing of thrombin. In this case, the binding of thrombin resulted in a significant increase in the anisotropy of the bound probe. The sensor could detect thrombin over three decades of concentration with a detection limit of 5 nM, and required only 10 µL of sample. Based on these values, absolute detection limits of 0.7 amol of thrombin were achieved.

The advantages of DNA based sensors, particular in comparison to other affinity-based systems such as antibodies, is that the binding is inherently reversible, and the biomolecule is far more stable than a protein. In fact, it has been reported that DNA sensors can withstand...
sonication or autoclaving with no loss in sensitivity, and remain stable for periods of over a year.\textsuperscript{119}

5.7 Multianalyte Sensing with Fluorescent Sensor Arrays

One of the most exciting advances in the area of fluorescence-based biosensors is the development of multianalyte sensors utilizing optical arrays. Such sensors combine two or more different selective chemical regions into a single device, and bring together the areas of device engineering and signal processing to create new devices. Early versions of multianalyte sensors were first described by Li and Walt.\textsuperscript{123} This early work used two or three different selective reagents immobilized onto individual polymer pads placed at the tip of an optical fiber. Imaging with a CCD camera gave intensities from each spot, which could be analyzed to give the concentration of multiple analytes. Since this time, a number of multianalyte sensors, sometimes referred to as “artificial noses”, have been reviewed.\textsuperscript{124} Most systems have relied on spatial discrimination of individual elements within the array. For example, Narang et al.\textsuperscript{125} have described fluoroimmunosensor arrays composed of different sensors for simultaneous detection of explosives such as hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) and TNT, and for simultaneous detection of clinically relevant species such as enterotoxin B (a common food poison), \textit{Yersinia pestis} F1 antigen (an agent of plague), and D-dimer, which can cause pulmonary embolisms and myocardial infarction when present at high concentrations.\textsuperscript{126} In the latter case, measurements could be done in whole blood, and the analytes could be quantitated over the physiologically relevant range covering 50 to 1000 ng mL\textsuperscript{-1} with detection times of 15 to 30 min.

Recent examples of arrays have used other methods of discriminating between different selective reactions within an array. In one case, randomly dispersed microbeads were prepared with different ratios of two fluorescent dyes.\textsuperscript{127} Beads with ratio A were derivatized with chemistry A, those with ratio B had a different selective biomolecule B attached, and so on. Discrimination of different chemical reactions was done on the basis of different fluorescent signatures from the beads. Using such an approach, Walt recently demonstrated the ability to construct an array of beads within small cavities formed in individual fibers of an optical imaging fiber bundle, shown schematically in Figure 5. As many as 20,000 beads could be deposited and individually addressed. In this case, three different selective chemistries were used. However, based on the ability to distinguish different spectroscopic signals from differently modified beads, it should be possible to simultaneously detect up to 150 different analytes using this approach.

6 COMPARISON WITH OTHER METHODS

The advantages and disadvantages of fluorescence-based biosensors can be determined either by comparison with sensors utilizing other transduction strategies, or by comparing such sensors to other analytical techniques. In the first case, it is prudent to compare the abilities of fluorescence-based sensors to those of sensors utilizing electrochemical, piezoelectric, or SPR techniques for signal transduction. In terms of sheer numbers of reports in the literature, fluorescence-based sensors are still a distant second compared with electrochemical sensors.\textsuperscript{128}

Electrochemical sensors are still the only commercially available systems for home monitoring, and have the advantage of being able to detect species without the need for labeled analogs or analytes, or labeled proteins. Other advantages include immunity to background signals associated with stray light and biological autofluorescence. Electrochemical sensors often have similar analytical

\textbf{Figure 5} Schematic (a) side and (b) top view of a randomly addressable multianalyte sensor based on an optical imaging fiber and individual fluorescent beads. The pattern of fluorescent beads, as shown in (b), is imaged with a CCD camera. The encoding dye within the bead identifies the analyte associated with a given bead, while the intensity of the analyte signal from an individual bead can be used for analyte quantitation. (Adapted from Michael et al.\textsuperscript{127})
characteristics (LOD, dynamic range) as fluorescence-based sensors, and suffer some of the same problems, particularly with regard to biomolecule stability. Other limitations inherent to electrochemical sensors are the need for a redox reaction for signal generation, and the inherent sensitivity to electrical and electrochemical interferences. Other areas where fluorescence signals offer unique advantages are in the development of intracellular sensing schemes, and the production of high-density arrays. Multianalyte sensors based on electrochemical signals have been described\(^\text{128}\) but are not as advanced as the arrays which utilize optical imaging fibers for discrimination of multiple analytes.

Comparison of fluorescence-based sensors to piezoelectric or SPR-based sensors shows some of the key advantages of the fluorescence transduction method. The major advantage of piezoelectric or SPR-based sensors is that they do not require labels. However, the lack of labels can also be seen as a drawback, since a limited amount of information is obtained from these techniques. In the case of SPR, one measures a change in “optical mass” (a combination of thickness and refractive index) upon analyte interaction with a surface. The signal itself is not information-rich, and it requires that the analyte have sufficient mass, generally over 10,000 MW, in order to produce a signal. Detection of small compounds such as drugs or metabolites is not possible with this method. Piezoelectric sensors rely on changes in mass at a surface, and are exquisitely sensitive when operated in the gas phase. However, most of the important applications for biosensors require operation in the liquid phase, where the operation of piezoelectric devices is not well understood.

A comparison with other analytical techniques can also be made. A key competitor is the enzyme-linked immunosorbent assay (ELISA), which is a standard sandwich assay where the secondary antibody is conjugated to an enzyme rather than a fluorescent probe. These systems can provide higher sensitivity than sandwich fluoroenzymeimmunoassays owing to the inherent amplification resulting from the enzyme catalyzed reaction. However, these systems are limited to analytes with molecular weights in excess of ~10,000 Da, since the analyte must have at least two sites for binding of antibodies. Fluoroimmunoassays, on the other hand, can be engineered to allow detection of virtually any substance. ELISA systems are also unsuitable for intracellular studies.

Other typical analytical methods for determination of organic compounds involve hyphenated techniques, such as liquid chromatography/mass spectrometry and GC/mass spectrometry. While these are extremely powerful techniques, and are often able to provide quantitative information for species present in relatively complex matrixes, there are still problems related to separation efficiency and matrix interferences (particularly if one wishes to analyze whole blood), and such methods are expensive and relatively time-consuming. Such methods are not well suited to continuous analysis, and the fact that they consume sample means that they are not reversible. Finally, such methods are not amenable analysis in remote locations, such as the inside of a cell.

7 SUMMARY AND FUTURE PROSPECTS

The development of fluorescence-based biosensors is a growing field that has not yet reached maturity. While most of the work in this area still occurs in the labs of academic institutions, a few commercial devices are now beginning to appear (for example the Ocean Optics oxygen and pH sensors), even though these are chemical sensors as opposed to true biosensors. The commonly employed methods of adapting standard enzyme and antibody-based assay technologies to a sensor format is slowly starting to wane, and a new generation of sensors utilizing proteins that are specifically engineered for sensing purposes is beginning to emerge. This new generation of fluorescence-based sensors is already starting to address some of the long-standing problems with sensor development, including the need for added reagents, and the lack of reversibility for some affinity-based sensors. Work is also under way in the development of improved proteins and immobilization technologies that may alleviate the problems associated with biomolecule stability. Key growth areas for this technology in the next decade will involve the development of quantitative gene chip technologies and improvements in multianalyte sensors, which may be used for quantitative identification of drug leads.

Recent advances in instrumentation are also likely to impact favorably on sensor development. These include the development of low cost fluorescence polarization-based instrumentation,\(^\text{129}\) and the application of fluorescence lifetime measurements to fiber-optic sensing.\(^\text{130}\) Such instruments reduce many of the problems associated with intensity-based measurements, such as artifacts arising from photobleaching and instrument drift. Other advances include interfacing of flow injection analysis systems to sensors to improve sample introduction,\(^\text{131}\) combining sample preparation methods such as solid-phase micro extraction\(^\text{132}\) or high-performance liquid chromatography\(^\text{133}\) with sensors to improve selectivity, and the development of array-based instruments capable of multianalyte detection.\(^\text{134}\) Each of these instrumentation advances makes new applications possible, and improves the reliability of sensors in established applications. Such developments are
sure to provide a bright future for fluorescence-based biosensors.

High-performance Liquid Chromatography of Biological Macromolecules

Knut Irgum
Department of Chemistry, Umeå University, Sweden

1 INTRODUCTION

Liquid chromatography (LC) with its modern counterpart, high-performance liquid chromatography (HPLC), has its roots in the biosciences. Although the discovery of LC is often attributed to the Russian botanist Mikhail Tswett shortly after the turn of the twentieth century, liquid phase chromatographic separations can be traced back to Runge, Goppelsröder and Schönbein in the 1860s. A recent survey shows that numerous separations of biological macromolecules were done during the later part of the nineteenth century using “capillary analysis”, a term used to describe a paper-chromatographic...
procedure remarkably similar to the technique for which Martin and Synge were awarded the Nobel Prize in 1952. The term “chromatography” (from Greek chroma and grafein) was coined by Tswett because he used the technique for separating different-colored plant pigments. Although he may not have invented LC, Tswett should be given credit for having converted adsorption chromatography into a more practical procedure. This was done by packing insoluble inorganic particles in a column, to which mixed solutes were applied and separated by elution with a solvent, the characteristics of column LC.

Chromatography in the liquid phase was practiced with relatively large particles under gravity flow for many years, and the development into HPLC as we know it today took place during the late 1960s and the 1970s. Characteristic of HPLC is that columns are packed with small, evenly sized material, through which eluent is driven by hydraulic pressure, often as high as several tens of MPa. When HPLC was introduced in the 1970s, it was rapidly established as a refined way of performing liquid phase chromatography, and the rationale for coining the term “high performance” was obviously the vastly improved separation power that could be achieved using smaller and more narrowly size distributed separation materials. This provided a level of resolution unachievable with low-pressure or open-column systems commonly in use at that time. However, improved separation does come at a price and it was paid for by high pressure, which has sometimes been used as an expansion of the first two letters of HPLC.

In parallel with the developments in LC, a rapid evolution also took place in separation techniques based on partitioning from the gaseous phase. For small molecules that are volatile and stable enough to be separated based on differences in vapor pressure and polarity, gas chromatography (GC) is frequently the separation technique of choice. However, as volatility is connected to the molecular size and polar functional groups of the solute, GC cannot be used for separation of large and temperature-sensitive compounds. Biochemical and biomedical applications have therefore remained the primary application area for HPLC, and separation of biomacromolecules by HPLC is consequently a large and expanding field.

The term “biological macromolecule” is ambiguous. For instance, the International Journal of Biological Macromolecules defines its scope as “proteins, carbohydrates, nucleic acids, viruses and membranes”. Of these structures, only the former three can be classified as solitary macromolecular entities. Viruses and membranes are multimolecular structures and will not be treated here, although many of the components that constitute such structures fit the scope of this article. Recent reviews of protein aggregate separation by chromatography following chemical cross-linking, separation of bacteriophages and related particles, and the use of cells and biomolecular assemblies as stationary phases can serve as entry points to this literature.

It is also necessary to define a limit in the lower end of the molecular weight scale, a distinction that perhaps is even more ambiguous. One might argue, for example, that eicosanoids and triglycerides are macromolecules, as they are larger than many peptides, but they are considered as compound classes of their own and thus not included. Through development of advanced techniques such as solid phase synthesis and the polymerase chain reaction (PCR), it has become possible to synthesize and multiply molecules entirely in vitro that are identical to biological macromolecules. Although these molecules can hardly fit the title of this treatise in a strict sense, they should still qualify as biological macromolecules. Consequently, the classes of compounds dealt with are natural and synthetic peptides and proteins, oligo- and polynucleotides, and oligomers and polymers of carbohydrates and their adducts with proteins. Worth noting at this stage is that many materials used for the separation of biomacromolecules are made from polymers or crystalline structures of biological origin, such as agarose, dextran, cellulose, chitin, chitosan, diatomaceous earth, and cattle bone.

HPLC has also been launched commercially under different acronyms. An example is “fast protein liquid chromatography” (FPLC), which differs from regular HPLC mainly by being performed on instrumentation designed to suit the particular needs of biochemists. There are also techniques that are adjunct to HPLC, such as capillary electrophoresis (CEC), micellar electrokinetic chromatography (MEKC), countercurrent chromatography (CCC), and some modes of field flow fractionation (FFF) which could have been part of this overview. However, this treatise will have to limit itself to hydraulically driven techniques employing a liquid eluent, and a rigid solid or gel as a stationary phase.

Because of the importance of the area, HPLC of biological macromolecules has been the subject of a large number of books and recent review articles of a general nature, as well as works providing overviews of the different subtechniques of HPLC and separation of specific compound groups to a depth not possible in this article. References to works dealing with specific separation modes or analyte groups are given in the relevant sections. There is also a multitude of books covering HPLC theory in general, as well as books describing HPLC with a distinctly practical approach. These references should be useful both
to seasoned practitioners and newcomers to the field. Finally, the classic text by Snyder and Kirkland is still well worth referring to. The number of references possible to provide in this format is limited. When choosing between “original work” and recent papers central to the technique, the latter have often been chosen, as this provides a better route into the literature.

2 DEVELOPMENT MODES IN COLUMN CHROMATOGRAPHY

There are several ways of applying samples to a chromatographic column and subsequently developing the chromatogram. The most common way of separating substances in HPLC is elution chromatography. However, other modes of development are also applicable in high-resolution bioseparations. The more important of these techniques are frontal chromatography and displacement chromatography. Both these techniques stem from the early days of chromatography but remain useful even today, in particular for preparative applications. In addition to the general elution principles outlined here, some separation chemistries may be amenable to more specific development schemes, such as chromatofocusing, which is a variation of gradient ion-exchange chromatography (IEC).

2.1 Frontal Chromatography

A frontal chromatographic experiment commences by equilibrating the separation material with a solution containing a replenisher that is weakly adsorbed onto the column. The column bed is then flushed continuously with a solution containing a mixture of the solutes to be separated. The separation is based on relative affinity to the stationary phase, and solutes that are interacting more strongly than the displacer with the stationary phase will replace the displacer compound and become attached to the column. When a larger volume of the solute mixture is applied to the column, solutes will act as displacers for each other. Consequently, the most strongly retained solute will occupy the sites at the top of the column, whereas more weakly interacting compounds are being forced further down to find their attachment sites. The process evolves as described in Figure 1.

The advantage of frontal chromatography is the high capacity, because a large part of the sorption capacity of the column is used simultaneously in the separation process. The main disadvantage is the inability to isolate compounds other than the most weakly retained solute, unless a separate eluent compound is used. In that case the technique changes to displacement chromatography.

![Figure 1 Diagram of the elution process in frontal chromatography. As the sample containing a mixture of solutes A, B, and C is pumped into the column, the solutes arrange themselves according to increasing affinity to the stationary phase, with the least strongly retained solute (A) eluting first, followed by more strongly retained compounds (B and C). The first solute (A) breaks through when the combined amount of solutes pumped equals the sorption capacity of the column. Only this solute emerges fully separated from the other. Subsequent bands contain the compound currently being eluted plus the previously eluted solutes at their concentrations in the sample. After a frontal separation, the column is conditioned for the next run by a replenisher (R) capable of removing the most strongly retained solute from the column.](image-url)

2.2 Displacement Chromatography

As just mentioned, displacement chromatography is an extension of frontal chromatography and starts by loading the separation column with a sample slug that becomes adsorbed in a frontal chromatographic fashion. An eluent is thereafter applied, containing a displacer compound having a ligand affinity higher than that of any of the adsorbed solutes in the separation column. This sequentially elutes the solutes as adjacent rectangular bands in order of increasing affinity for the column ligands, entrained by the displacer. After the separation is completed, the separation column is prepared for the next cycle by flushing out the displacer with a regenerant solution and re-equilibration with the mobile phase. The procedure is shown in Figure 2. This can be a lengthy procedure unless a reaction can be used to alter the displacer affinity, as the regenerant should replace the displacer by a substantially more weakly attached compound. Although displacement...
Figure 2 Diagram of the separation process in displacement chromatography. The column is loaded with a sample slug containing a mixture of solutes and is then flushed clean with a noneluting solution, followed by pumping of a displacer, which selectively elutes one or more of the absorbed solutes from the column. The solutes are displaced as bands, the widths of which are related to the solute concentration. After a separation run, the displacer must be removed from the column to enable sorption of solutes in the following run.

Displacement chromatography is an important development mechanism in affinity separation schemes, in downstream processing, and in solid phase extraction (SPE) related to sample preparation where it is used to isolate solutes of interest and eliminate sample matrix components. An interesting recent development in displacement chromatography of proteins is the use of dendritic polymers and block copolymers of methacrylic acid, methyl methacrylate, and 2-(dimethylamino)ethyl methacrylate as eluting parties in hydrophobic interaction chromatography (HIC). Such designed displacing agents show a way toward biomimetic interactions with sorbents, providing for other selective elution techniques in the future.

2.3 Elution Chromatography

In elution chromatography, the sample is introduced in a finite volume plug at the head of the separation column, whereafter a suitable eluent is used to force the sample components through the column at solute-specific migration speeds, which are determined by the flow rate of the eluent and the distribution of solute between the mobile and stationary phases (Figure 3). The elution can be carried out isocratically (i.e. with eluents of constant composition) or by varying the concentration of one or more of the components in a stepwise or continuous gradient fashion, often involving several gradient segments. The similarity between displacement elution and gradient elution is obvious.

Isocratic elution is rarely used for elution of biomolecules in chromatographic modes involving sorption equilibria (partitioning), for reasons explained below. The separation efficiency would be too low due to mass transfer limitations caused by the low diffusion rates of
large molecules. Large differences in partition coefficients of macromolecules also make it difficult to separate even similar components using an isocratic eluent.

2.3.1 Gradient Elution

An eluent gradient \(^{(63)}\) can be formed by varying the solvent composition in the eluent during a run, but more common in the elution of biomacromolecules is to vary the concentrations of salts, acids or bases, or other ancillary agent added to the solvent, which is often water. Gradient elution can also be accomplished by alterations in physical parameters such as temperature \(^{(64,65)}\) and/or flow rate. \(^{(66)}\) Linear gradients are often used, but modern instruments are capable of forming gradients of complex shapes with segments of different steepness, curvatures, step changes, and plateaus. Optimization of gradient elution is dependent on the chromatographic mode used, and a slow linear gradient is a sound first attempt for most biomacromolecule separations. If a fast gradient is used and solutes are adsorbed irreversibly, a judicious effort at improving the recovery would be to decrease the steepness of the gradient. The reason for this is best explained by studying the shape of the retention versus eluent concentration for curves B and D in Figure 46 below, along with the text adjoining that figure. Examples of gradients with many different shapes are found in the chromatograms presented later in this chapter.

Eluent demixing \(^{(67)}\) is a phenomenon that takes place when the strong component of an eluent is retained on the separation material in a frontal chromatographic fashion, causing the eluent composition at the column outlet to deviate from the programmed shape. For instance, if a mobile phase with a linearly changing composition is pumped through the column, the shape of the concentration profile after passing the sorbent bed will often not reflect the composition at the column head, but instead emerge with a slower than intended increase during the initial part of the run followed by a steep step increase (a shock layer), after which the shape will follow the programmed shape with reasonable fidelity. The sudden concentration increase caused by demixing can lead to artifacts in the central part of a chromatogram, which can be seen as noticeably narrower peaks, shoulders, low recovery, or impaired resolution in this region. \(^{(68)}\) The extent of demixing is dependent on depletion of the strong component from the stationary phase and will decrease if the weak eluent does not contain the strong eluent component, or if it is present at low concentration. IEC is particularly sensitive to demixing if eluent ions with different affinity for the fixed ionic groups are used in a gradient. \(^{(69)}\) It is also important to thoroughly equilibrate the column with the weak eluent between each gradient run. If complete equilibration cannot be accomplished due to slow replacement of the stronger eluent component, the time between injections should at least be kept constant.

2.4 Viscous Heating and Column Thermostatting

Column temperature is also a source of concern. Properties of biological macromolecules are affected by temperature, and changes in protein conformation, melting of DNA, thermally controlled aggregation, etc. will influence the retention. Temperature is thus one of the optimization parameters (which is also evident from Equation 6). When the temperature is varied, attention should be paid to viscous heating, which occurs as the solvent forces its way through the packed bed \(^{(70)}\) and can lead to a column temperature higher than expected. The power generated by the pump (i.e. the pressure drop times the flow rate) is converted into heat that is partly dissipated by heat exchange through the column walls and partly by the eluent itself. Due to this dual heat dissipation mechanism, both axial and radial temperature gradients can be encountered in columns. The magnitude of these thermal gradients will depend on back-pressure, flow rate, temperature, and thermal capacity of the eluent, the material, diameter and length of the column, and the preset temperature and efficiency of the column thermostatting device. Large-diameter columns with small particle-size sorbents are most affected by these effects.

2.5 Fundamental Chromatographic Thermodynamics

In order to rationalize many of the modern directions in chromatography of biological macromolecules, it is necessary to provide a brief background to the mechanisms that control retention and band broadening in elution HPLC. The data required to determine these thermodynamic and kinetic performance parameters of a column are acquired by running a set of test solutes under isocratic conditions. A chromatogram should thereby be obtained with peaks for the individual solutes, as shown in Figure 4.

By adding a suitable marker substance that passes the column without retention and is visible in the detector, we can determine the void time, \(t_v\). The retention times \(t_r\) for the solutes must also be obtained, by measuring the time elapsed from the injection to the apex of the peak of the respective solute. (The retention time should actually be based on the center of gravity of the peak, but for Gaussian peaks like those shown in Figure 4 the peak apex and the center of gravity coincide. Determination of the dead volume is not uncomplicated either; general texts on HPLC discuss these problems.) For each peak, we then proceed by extracting the peak width, either at the base \(t_a\), or at half the peak height \(t_{0.5\%}\). With these
data we can for each solute calculate its capacity factor \( k' \), which is a dimensionless number used to normalize the retention by making it independent of flow rate and column volume (Equation 1):

\[
k' = \frac{t_r - t_0}{t_0}
\]  

(1)

What \( k' \) actually describes is the ratio of time spent by the solute in the stationary phase to the time spent in the mobile phase. For this to be accomplished, there has to be an identical ratio between the number of solute molecules in the stationary phase, \( n_s \), and in the mobile phase, \( n_m \), as the solute traverses the column (Equation 2):

\[
k' = \frac{n_s}{n_m}
\]  

(2)

 Considering the volumes of the mobile \( V_M \) and stationary \( V_S \) phases, and the phase ratio \( \Phi \) which is the quotient of these two volumes, it is possible to express \( k' \) as \( \Phi \) times the equilibrium constant \( K \) of the partitioning reaction, i.e. the ratio of the molar concentrations of solute X in the two phases of the column (\([X_S]\) and \([X_M]\), respectively), as in Equation (3):

\[
k' = \frac{[X_S]V_S}{[X_M]V_M} = \Phi \frac{[X_S]}{[X_M]} = \Phi K
\]  

(3)

A prerequisite for obtaining separation between a pair of solutes is obviously that they have different \( k' \), and the degree of separation is expressed by the selectivity coefficient \( \alpha \) as

\[
\alpha = \frac{k'_2}{k'_1}
\]  

(4)

In Equation (4) the value of \( \alpha \) is always \( \geq 1 \), because \( k'_2 \) refers to the last eluted peak of the pair under consideration.

As \( K \) is related to overall energy change of the separation process through the Gibb’s equation (Equation 5),

\[
\Delta G^\ominus = \Delta H^\ominus - T \Delta S^\ominus = -RT \ln K
\]  

(5)

we can relate \( k' \) directly to the fundamental thermodynamic parameters of the separation process through Equation (6):

\[
\ln k' = \frac{\Delta H^\ominus - T \Delta S^\ominus}{-RT} + \ln \Phi
\]  

(6)

The selectivity according to Equation (4), i.e. how different solutes distribute between the mobile phase and the stationary phase, is thus related to the thermodynamics of the separation process. Equation (6) shows how the enthalpic and entropic contributions affect the separation, which can be mediated by sorption, repulsion, exclusion, or other processes in the column. Differences in Gibb’s free energy of sorption are thus required for solutes to separate from each other according to Equation (7),

\[
\log \alpha = \frac{|\Delta (\Delta G^\ominus)|}{RT} = \frac{|\Delta (\Delta H^\ominus) - T \Delta (\Delta S^\ominus)|}{RT}
\]  

(7)

an energy difference that can obviously come from differences in heat of sorption (enthalpy, \( \Delta (\Delta H^\ominus) \)) or from changes in order (entropy, \( \Delta (\Delta S^\ominus) \)). Apart from their utility as separation tools, chromatographic techniques are consequently powerful means for obtaining fundamental thermodynamic parameters from sorption processes. For instance, van’t Hoff plots (\( \ln k' \) versus \( 1/T \))
are common when assessing the retention as a function of temperature.\(^{(71)}\) An important point is that the parameters obtained in this way are valid only for the solutes tested, and under the specific conditions used during the test.

2.6 Macromolecules and Mass Transfer in Chromatography

Whereas the thermodynamic factors just discussed are responsible for establishing the selectivity of a separation process, its efficiency, i.e. how well an injected sample zone is kept from broadening as it traverses across the separation column, is controlled by kinetic and fluid dynamic factors. This is why the peak width data that were extracted in Figure 4 have not yet been used. In most separation modes the peak width is not related to differences in the column equilibria, but to limitations in mass transfer, sorption kinetics, and flow dynamics of the flow system downstream from the point of injection. Band broadening will occur whenever the zone initially injected is distributed across a larger part of the column than the originally injected zone. This dispersion can have its explanation in processes taking place in the column, but also in extracolumn effects originating from less than optimal system plumbing. Only the band broadening that occurs inside the column will be treated here. Guidelines to avoid extracolumn band broadening are found in general HPLC texts.

The common measure of separation efficiency of a separation column is the number of theoretical plates \(N\), which can be derived from \(t_r\) and the time variance \(\sigma^2\) of an injected band or, alternatively, from the width of the peak at the base, \(t_w\):

\[
N = \left( \frac{2}{\sigma^2} \right) = 16 \left( \frac{t_r}{t_w} \right)^2 = 16 \frac{t_0(1 + k')}{t_w}^2 \quad (8)
\]

The last equality in Equation (8) shows a way of obtaining \(N\) from \(k'\) and \(t_0\), instead of \(t_r\). An alternative to using \(t_w\) is also to use the width at half the height \(t_{w/2}\), in which case the constant 5.54 is used instead of 16.

The concept of theoretical plates is derived from distillation theory and visualizes the number of separation instances that a solute experiences on its way through the column. A common way to describe the quality of a column packing without having to know the length \(L\) of the column is to calculate the height equivalent to a theoretical plate, \(H\), whose inverse relationship with \(N\) means it should be as low as possible to obtain good column efficiency (Equation 9):

\[
H = \frac{L}{N} \quad (9)
\]

In order to compare column packings with different particle diameters, it is convenient to use the reduced plate height \(h\), which is the height equivalent to a theoretical plate divided by the particle diameter (Equation 10),

\[
h = \frac{H}{d_p} \quad (10)
\]

as well as the reduced velocity \(v\), which is a product of the linear flow velocity \(u\) (equal to \(L\) divided by \(t_0\)) and the particle diameter, divided by the diffusion coefficient of the solute in the mobile phase \(D_m\) (Equation 11),

\[
v = \frac{ud_p}{D_m} \quad (11)
\]

The factors contributing to the reduced plate height can then be modeled as functions of the reduced velocity by the van Deemter–Knox equation\(^{(72)}\) (Equation 12):

\[
h = A v^{1/3} \rightleftharpoons + B \frac{1}{v} + C v \quad (12)
\]

The enemies of a good separation are all the factors that act towards an increase in \(h\), and the important ones are shown schematically in Figure 5.

The factor \(A\) in Equation (12) relates to the band broadening resulting from eddy diffusion, whereby solutes are dispersed along the packing as the mobile phase percolates the stationary phase particles in a tortuous flow, where the different eluent flow streams experience pathways of varying flow resistance between the particles. The value of the constant \(A\) is roughly proportional to the particle diameter \(d_p\) (Equation 13):

\[
A \propto d_p \quad (13)
\]

![Figure 5](image_url) Diagrams of the factors that contribute to band broadening of a solute zone in a packed column. (Reproduced from C.T. Mant, R.S. Hodges, HPLC of Peptides and Proteins: Separation, Analysis and Conformation, 101, 1991, by permission of CRC Press.)
The eddy diffusion term is also affected by the shape of the particles and the quality of packing. A well packed column bed of small, uniformly shaped particles thus produces the lowest contribution to eddy diffusion.

The second term, $B/v$, relates to the axial diffusion in both phases. However, the most important contribution originates in the mobile phase, due to diffusion and Brownian motion. The inverse relationship with the reduced velocity reflects lower peak dispersion when the linear flow rate of the eluent is increased because the time available for diffusion decreases. The magnitude of $B$ is also proportional to $D_m$ (Equation 14):

$$B \propto D_m$$

Some representative values for diffusion coefficients of various biological compounds in water are listed in Table 1. It is evident that large molecules such as proteins may diffuse up to several orders of magnitude slower than small molecules.

At very low eluent flow rates, the factor $B$ may become significant for small molecules. In separations of biological macromolecules, characterized by low diffusion coefficients, mass transfer resistance outweighs longitudinal diffusion for all practical separation situations. The separation efficiency for large molecules is thus largely controlled by the third term of the van Deemter–Knox equation, $C_v$, which relates band broadening to mass transfer resistance.

An important reason why peaks broaden can be found in local deviations from equilibrium across the solute band. If an ideal linear sorption isotherm is considered, which incidentally will hardly ever occur in the separation of biomacromolecules, the solute concentrations in the stationary phase should mirror concentrations in the mobile phase across the solute band as visualized in the left part of Figure 6, with a concentration ratio $K$ according to Equation (3). This represents the ideal case. However, associated with the surface of a particle is a layer of nonmoving mobile phase, surrounded by a film of liquid flowing slower than the bulk flow. Whenever a solute diffuses from the bulk mobile phase into these regions of lower flow velocity, it will experience retardation relative to the bulk flow due to reasons unrelated to the partition process. Further, if the stationary phase is porous, there are regions in the intraparticle space where the mobile flow is essentially immobile (stagnant pools) through which a solute must diffuse in order to interact with the stationary phase. As the mobile phase flows continuously while these processes take place, the column equilibrium is perturbed and the concentration within the stationary phase will be different from that of the compound in the mobile phase. This eventually leads to dispersion of the injected solute along the column, as the system attempts to reach equilibrium. This process is illustrated in the right part of Figure 6. Deviation from local equilibrium depends on the overall kinetics of the partitioning reaction within the column and is particularly important for biomacromolecules, because of their low diffusion rates. Factors that make up for the factor $C$ in Equation (12) involve contributions from different impeding processes (Equation 15):

$$C = \frac{k_1d_p}{D_m} + \frac{k_2d_s}{D_s} + k_3$$

The first term is related to the mass transfer in the mobile phase, for which there is an inverse relationship with the solute diffusion rate in the mobile phase and a quadratic dependence on particle size. The second represents the band broadening due to mass transfer limitations in the stationary phase. Here again, an inverse relationship with

Figure 6 Illustration of the offset in concentration profiles across eluting peaks due to nonequilibrium conditions caused by the moving eluent in combination with mass transfer limitation. The left curve shows the ideal case, where the mobile and stationary phase concentrations are mirrored according to an ideal linear adsorption isotherm. In the right part of the figure, the mobile phase concentration profile runs ahead of the concentration profile in the stationary phase because of a finite mass transfer rate between the phases, leading to band broadening. (Reproduced by permission from Karger.$^{73}$)
the diffusion coefficient of the solute applies, this time in the stationary phase $D_s$. There is also a quadratic contribution from the stationary phase interaction layer thickness $d_i$. However, the interaction layer thickness can in general be neglected for biomacromolecules, because the interaction of these molecules with a rigid stationary phase typically takes place as a monolayer process at the surface of the pore system of the support. The third term is due to the kinetics of the actual interaction process, and can also be considered insignificant, unless the formation and breaking of covalent bonds or multiple strongly oriented interactions are involved in the sorption process, as in affinity chromatography.

In summary, the factors that lead to minimization of $h$, thus promoting a better separation efficiency, are:

- **Smaller particle size** – Minimizes the eddy diffusion and makes the mobile phase mass transfer more efficient. The penalty is a higher operating pressure and, ultimately, a risk of clogging the separation column.
- **Decreased mobile phase flow rates** – The influence of the mass transfer resistance term decreases as the flow rate is lowered. There is also an inverse relationship to flow rate in the factor $B$, but mass transfer resistance contributes far more to band broadening than longitudinal diffusion under normal HPLC flow rates – particularly for macromolecular solutes. The trade-off is slower separation and a higher risk of denaturation of proteins.
- **High solute diffusion rates in the mobile phase** – Solutes can partition more readily. At very low flow rates, increased $D_m$ leads to more dispersion by longitudinal diffusion. Under flow rates typical of HPLC, this term is insignificant. Besides, $D_m$ is a fundamental property of a solute, not an easily accessible experimental variable.
- **Low-viscosity mobile phases** – The $D_m$ is a function of the mobile phase viscosity, which in turn depends on the temperature. Increased temperature usually leads to more efficient separations, but also increases the likelihood of conformational changes and denaturation of biopolymers. The same applies to the use of low-viscosity organic solvents.
- **Shallow and permeable stationary phase films** – Stationary phases with superficial (pellicular) interaction layers or particles with convective internal flow (see below) minimize the intraparticle diffusion pathways. Gel networks should be sufficiently permeable to avoid diffusion limitations.

More detailed treatments of the kinetics in LC of biopolymers can be found in appropriate texts.$^{[76]}$

### 2.7 Solubility Properties that Distinguish Macromolecules from Small Solutes

In spite of the mass transfer limitations just mentioned, practitioners of HPLC familiar with the separation of small molecules may be surprised by the high separation efficiencies that can be achieved for biopolymers on columns of odd dimensions,$^{[77,78]}$ with particles of awkwardly large size, and under low back-pressure,$^{[79]}$ conditions quite different from those considered typical of HPLC of small molecules. The reason why such unconventional media formats can be used in biomacromolecule separations is to be looked for, at least partly, in the solvation mechanisms of macromolecules, and in utilization of multiple contact points for the interactions between the biomacromolecule and the stationary phase interaction layer.

The key to understanding how biomacromolecules behave in a chromatographic system is to recognize the mechanisms that keep these molecules in solution. Polypeptides and oligonucleotides are amphiphilic molecules having both hydrophilic and hydrophobic areas within the same molecule. This means that their surfaces exhibit areas with either polarity or heterogeneous charge distribution. Molecules in solution are solvated, i.e. they have to interact with the surrounding solvent molecules to stay in solution, and the process of transferring a molecule from the stationary phase into the mobile phase involves recreating a cavity for the molecule in the solvent. In polar solvents, where the intermolecular interactions are strong, breaking of bonds between solvent molecules can require substantial energy and the concomitant formation of bonds of similar strength to the solute. If the solute cannot provide for interactions acceptable by the solvent, a substantial amount of energy is required to form a cavity, and the transfer into the solvent is therefore unlikely. This, rather than the stationary phase hydrophobicity, explains why compounds without polar groups cannot dissolve in water, which is the highest-polarity solvent in common use in HPLC. Likewise, the process of dissolving a polar substance involves the breaking of polar bonds between solute molecules. This cannot be accomplished by a nonpolar solvent, which has no polar groups to offer as alternative bonding sites.

There is nothing unique to large molecules in relation to this general principle. The difference compared with small molecules lies in the concerted solvation action needed to stabilize a biomacromolecule with its many heterogeneous interaction sites. The stability of most biopolymers in solution is thus limited. Minor changes in the mobile phase are often sufficient to bring about an aggregation or a dissolution of a macromolecule, or to attach it to, or detach it from, a heterogeneous
surface. This affords excellent possibilities to achieve band separation, as determined by the selectivity factor \( \alpha \) through changes in Gibb’s free energy, according to Equation (7). The most important factors contributing to changes in Gibb’s free energy are electrostatic and van der Waals type interactions, solvation effects, formation of the solvent cavity around the biopolymer, its self-association and heterogeneous associations in the absence of solvent, and deviations from ideality in the sorption–desorption process.\(^{(80)}\)

The various energies involved in each interaction point between a macromolecular solute and the two competing phases are additive. The equilibrium process for a peptide or a protein P interacting with a stationary phase and its ligands L can thus be expressed by Equation (16),

\[
P\text{(Solv)}_a + nL\text{(Solv)}_b \leftrightarrow \text{P(Solv)}_{(a-f)} nL + (nb+f)\text{Solv}
\]

where \( P\text{(Solv)}_a \) represents a solute with \( a \) moles of bound solvent (typically water in biomacromolecule separations) or solvated ions, \( nL\text{(Solv)}_{a-f} \) represents the ligand attached to \( b \) moles of solvent or eluent ions, \( f \) is the number of solvent molecules or eluent ions released from the solute when binding to the ligands, and \( P\text{(Solv)}_{a-f} nL \) represents the partially solvated solute attached to the immobilized ligands.

Interactions between the biomacromolecule and the mobile phase are equally important as its interactions with the ligands located on the sorbent surface. It has been found empirically that within the retention factor range \( 0 < k^\prime < 20 \), the relationship between \( k^\prime \) and the displacing agent concentration \( c \) can be described by the following approximately linear relationship,

\[
\log k^\prime = A + B \left( \log \frac{1}{c} \right)
\]

Equation (17) applies to widely different interaction modes\(^{(81)}\) such as ion exchange (see below for a more elaborate discussion of the \( Z \) value in this separation mode; Equation 18),

\[
\log k^\prime = \log k^\prime_{\text{0,EX}} - Z \log [\text{salt}]
\]

reversed phase (RP) (Equation 19),

\[
\log k^\prime = \log k^\prime_{\text{0,RP}} - M \log [\text{solvent}]
\]

and separations based on hydrophobic interactions (Equation 20),

\[
\log k^\prime = \log k^\prime_{\text{0,HIC}} - H \log [\text{salt}]
\]

The terms \( k^\prime_{\text{0,EX}}, k^\prime_{\text{0,RP}}, \) and \( k^\prime_{\text{0,HIC}} \) represent the retention factors at unit concentrations of the displacing agents, where \( \log (\text{displacing agent}) \) is zero, and the stoichiometric retention parameters \( Z, M, \) and \( H \) are the sign-inverted slopes of the plots of \( \log k^\prime \) versus the logarithms of the salt or solvent concentrations. These figures are related to the number of contact points involved in the interactions between the solute and the stationary phase. The values of \( Z, M, \) and \( H \) are typically in the range 2–10 for biopolymers, which means that their retention can be altered considerably by changes in the eluent strength, as illustrated by Figure 7.

As a consequence of this steepness of the \( k^\prime \) versus eluent strength plots, biomacromolecular solutes often exhibit sharp transitions from soluble to associated or precipitated state according to the all-or-nothing principle coined by Tiselius,\(^{(82)}\) producing what can be regarded as traffic light chromatography. High performance does therefore not necessarily require the use of small particles and high pressure in separation modes designed for biomolecules, where multiple strong interactions are exploited and controlled by gradient elution. Nor are long columns required or even advantageous in gradient elution,\(^{(83)}\) as a single interaction instance is in principle sufficient for the capture and release required to accomplish separation. In such settings, high resolution can be achieved even using relatively large-size packing materials, shallow beds (sometimes even in the form of a membrane\(^{(84)}\)), and even soft gels.

When a chromatographic method is being developed, the required separation can be accomplished through a combination of selectivity, retention, and efficiency.

![Figure 7](image)

**Figure 7** Effect of acetonitrile concentration on the \( \log k^\prime \) values of a small molecule represented by propiophenone (A1), a decapeptide (P5), the protein apomyoglobin (ApoMb), and the heme group of this protein (Heme) eluted isocratically on a Brownlee Labs Aquapore RP-300 C\(_8\) (220 × 4.6 mm internal diameter (i.d.); 7 μm; 300 Å) column. (Reproduced from C.T. Mant, R.S. Hodges, *HPLC of Peptides and Proteins: Separation, Analysis and Conformation*, 7, 1991, by permission of CRC Press.)
suitable for that separation. For small molecules, the changes in solvation and sorption energy that occur when the solutes are transferred from solution to the stationary phase are often quite small and of similar magnitude for all compounds being separated. This means that the solutes will elute relatively close to each other in the chromatogram, enabling the use of isocratic elution. The principal impetus for such separations thus becomes efficiency, i.e. prevention of the narrowly spaced solute bands from dispersing into adjacent bands. In contrast, separations of biopolymers are most often controlled by selectivity. The separation chemistries are therefore more diverse and the process of finding suitable techniques and optimal conditions can consequently be arduous.

2.8 Stability of Biological Macromolecules

The stability of biopolymers, the need to preserve their native state during chromatographic separation, and ways of accomplishing this are important concerns for preparative and production-scale biomacromolecule separations. On the contrary, there is in analytical separations often no direct requirement to maintain the biomacromolecule in its native state, so long as the conformational changes are reproducible and manifest themselves in intermolecular interactions patterns that enable its separation from other solutes in the sample. Actually, a number of widely used analytical separation techniques such as sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) involve intentional denaturing of proteins in order to obtain a sample with more predictable properties.

The amphiphilic properties outlined above are responsible for the higher structural features of proteins. Whereas polar groups are exposed on the surface of a protein suspended in water to stabilize the molecule by solvation, the three-dimensional structure is maintained by intermolecular forces, partly from hydrogen bonding due to the peptide backbone, and partly from weak interaction between hydrophobic lateral chains. These interactions are usually stabilized by a relatively small number of salt bridges and covalent disulfide bridges. The structural stability originating from these concerted interactions can vary substantially – some proteins are so unstable that they can hardly be isolated from their natural environment without extensive denaturation, whereas others are surprisingly robust and can resist quite extreme conditions. The most stable overall configuration is achieved at the point of balance where the internal bond strengths, molecular strain, solvation, and other intramolecular interactions yield the lowest Gibb's free energy kinetically accessible to the polypeptide chains. Anything that changes the relative strength of these forces acting upon the molecule challenges the native configuration. A system this complex is prone to respond to any action that causes an alteration in charge, solvation, or internal bonding pattern. This means that solvent activities, salt concentrations, and pH are factors that should be under close control in protein separations.

Interaction of a protein with a surface means that some of the external functional groups will be reoriented from solvent coordination onto interaction points at the support surface, which may result in a strain in the molecule. Following the initial contact, the protein will experience attractive and repulsive forces at the surface, which drive the molecule to flex and yield in order to minimize the overall energy in its new environment. During this process, new contact points may be found which alter and augment the strain. No denaturation occurs if the protein can withstand these ordeals without altering its internal bonding pattern. However, any interaction producing an appreciable retention is likely to cause changes in internal bonding patterns, in particular for very large molecules. These alterations can aggregate over time in a chain of small conformational changes that may eventually modify the molecule from its original state to such an extent that a spontaneous reorganization, rendering the macromolecule back to its original shape, is impossible upon release from the surface. If so, the protein has transformed into a denatured state, which usually has catastrophic consequences for its biological function. New conformations are also likely to display interaction patterns with the stationary phase that are different from those expressed by the natural molecule. This is exemplified in Figure 8, where four proteins are chromatographed on an interaction layer comprised of short alkyl chains. In these chromatograms, the earlier-eluted peaks are the folded proteins and the later peaks are the unfolded (denatured) proteins. The peaks from the unfolded proteins increased at the expense of the folded proteins as the contact time between the proteins and the stationary phase was lengthened. Some stationary phases may exert such strong denaturing effects that proteins may fuse with their surface and cannot be eluted at all. If such denaturation is due to specific interactions with active residual sites on the interactive surface, sacrificing a readily available and inexpensive hydrophobic protein such as bovine serum albumin (BSA) can be a viable way to block the residual activity prior to using the column for separation of sensitive proteins.

Much of the development in HPLC of biomacromolecules has consequently focused on finding soft interaction modes for proteins, in which the delicate interaction–deformation balance is optimal. Interactions that utilize fast and reversible binding to groups exposed at the surface of the protein are far less dangerous than interactions based on inversion of the protein structure, i.e. extensive exposure of hydrophobic groups. Likewise, the use of solvents or other mobile phase additives that
break the internal protein structure are also factors that will lead to excessive denaturation. Temperature and contact time with the surface are obviously important in these processes, as the majority of these changes are associated with activation energies sufficiently large to maintain the molecule in a native state in the absence of perturbations. Minimizing the separation time is therefore central for maintaining conformation, because most bioseparations are based on initial capture by highly retentive multipoint interaction processes followed by gradient elution.

3 MOBILE PHASES – ELUENT

An eluent for the separation of biomolecules should fulfill all general requirements for HPLC eluents:

- low viscosity to promote solute diffusion in the mobile phase and provide for a lower back-pressure;
- miscibility with other eluent components;
- an ability to wet or swell the stationary phase;
- compatibility with the detection mode;
- inertness relative to the solutes and the stationary phase;
- low volatility to prevent cavitation and outgassing in pumps and detectors;
- an ability to dissolve buffer salts;
- an ability to solvate the macromolecular solutes without causing undesirable denaturation or breakdown;
- low toxicity;
- a reasonable cost of both purchase and disposal.

Properties of a large number of eluent candidate solvents can be found in the literature. Only a handful of organic solvents satisfy these stringent criteria. Water complies with most requirements and is also an ideal solvent from toxicological, environmental, and economic points of view. As most biomolecules discussed here exist in fully or partially aqueous phases, water is an obvious solvent choice, and in applications where proteins should be recovered in their native state, it is often the only solvent possible. Notable exceptions are membrane proteins, which need additional components for solubilization, and small peptides that require and can tolerate the use of polar organic solvents in reversed-phase high-performance liquid chromatography (RPHPLC). The most frequently used organic solvents in techniques requiring fully or partially nonaqueous phases are acetonitrile and the lower alcohols (methanol, ethanol, and 2-propanol). In rare cases, alkanes and lower-chlorinated alkanes are also used.

In chromatography of small molecules, the polarity of an eluent and thereby its strength are usually altered by varying the mixture of organic solvents, often with water as one of the solvent components. In contrast, in the area of biomacromolecule separation, it is more common to alter the polarity of water without adding any less-polar solvents, just by using polar nonionic compounds such as urea or ethyleneglycol, or salts with cosmotropic or chaotropic ions to cause salting in and salting out of the solutes. These agents act mainly by altering the structure and activity of water, and affect the solvation and self-aggregation tendencies (coloidal stability) of the biopolymers. They may also alter the retention by interacting with functional groups on the stationary phases.

4 SEPARATION COLUMN

The key to predictable high-performance separations in LC lies in a perfect control over the physicochemical
characteristics of the column and a sound insight into the processes that lead to sorption and desorption of biomacromolecules. Reproducibility in particle diameters, pore size distribution, and surface chemistry has improved tremendously over the years and particulate column packing materials are now almost exclusively made as spherical beads, ranging from micrometer-sized nonporous to gigaporous particles. Identification of porous properties as one of the key factors has led to materials with precisely controlled porosities, whereas the insight that chemical and morphological features of the interaction layers affect the reversibility in the biomacromolecule sorption has enabled new developments such as spatial location of orientated interaction layers with tailored interaction properties.

The most important decision that must be made during development of a separation method is the choice of separation mode, which directly implies the selection of a separation column. Choices have to be made with regard to support matrix, the functional groups and the morphology of the interaction layer (if any), and dimensions and material of the column. Factors that must be taken into consideration are the nature of the solutes and sample matrix, which determine the separation chemistry to be used, and the purpose of the separation, which determines the separation efficiency and sample capacity required. The sorption capacity of a separation material can be determined either as the static or as the dynamic capacity. The static capacity is measured in the batch mode, by measuring the adsorption of a protein probe such as BSA onto the material under conditions where sorption is strong. Dynamic capacity is the amount of material that the separation material will adsorb when pervaded by solution at a certain flow rate, i.e. under the conditions that the material will actually be used. There can be a substantial difference between the static and the dynamic capacities, reflecting the kinetics of the sorption process.

Other practical aspects influencing the choice of a column packing are compatibility with available detection modes and the required lifetime. When a method expected to have longevity is to be developed, it is furthermore essential that the same or at least similar column will be available over the lifetime of the method. This is particularly important in quality control, or in preparative separations such as downstream processing in biotechnology, where regulatory issues may restrict the degree of freedom in both the development and subsequent changes to the method. Industrial users are therefore adopting new techniques somewhat reluctantly, and proven and widespread principles are often preferred over new and uncommon techniques, although the latter may have better performance. More details are available in numerous monographs and recent review articles.

### 4.1 Choice of Support Matrix Material

Supports are best classified according to their morphology as soft, semirigid, or rigid gels. Soft gels (xerogels) are swollen, essentially homogeneous polymeric networks with solvent-imbibed interstices forming an isoporous system. Xerogels used in biomacromolecular separations with water as solvent are typically highly hydrophilic water-swollen networks that are termed hydrogels. In order to accommodate diffusion of biomacromolecular solutes, the cross-linking density of the material has to be low and, as a consequence, the rigidity of the network is insufficient to maintain its own structural integrity under stress. Xerogels therefore swell and shrink considerably with variations in solvent composition, salt strength, or other factors affecting the degree of internal solvation, and collapse when the solvent is removed. Collapsed xerogels are not always reswellable and permanent structural changes are often seen if the gels are allowed to dry. True xerogels are generally unable to withstand the differential pressures needed for HPLC separations.

In contrast, rigid gels (aerogels) are networks of stiff and dense material intersected by macropores into which solvents and solutes can penetrate. The rigid matrix volume of an aerogel does not change in solvents, and thus its dimensional and mechanical properties are retained in different eluents. The aerogel porosity also remains unchanged when the solvent is removed. Semirigid gels, such as partly swellable polymeric materials cross-linked through ordered crystalline segments, combine properties of both xerogels and aerogels. Although the amorphous regions swell in solvents and behave as a xerogel, the crystalline areas act as rigid aerogel-type reinforcing structures. Most synthetic polymers behave as semirigid aerogel–xerogel composites, as they swell in different solvents. The difference between xerogels and aerogels is shown schematically in Figure 9.

In interactive chromatography, the role of the support is usually to act as a carrier for the specific interaction layer, whereas in noninteractive (size exclusion) chromatography the support also constitutes the stationary phase. In either mode, only materials with well-controlled porous properties and surface chemistry can serve as high-efficiency HPLC sorbents. As outlined above, the prerequisites for efficient mass transfer are small-diameter particles, shallow interaction layers, and large enough pores for solutes to diffuse freely. In order to avoid pore crowding in interaction chromatography, a rule of thumb is that the average pore size should be 10 times the hydrodynamic diameter of the biomacromolecules under separation.
Figure 9 Diagrams of (a) soft gels (xerogels) and (b) rigid gels (aerogels). Xerogels are comprised of isoporous networks of randomly dispersed linear polymer chains connected by interchain cross-links at random intervals. The pores are sufficiently large to accommodate biopolymers. Aerogels are hard, impervious materials with high fractal dimension (i.e. resembling a cauliflower), where the particle is formed by an interconnected array of small microglobules. The voids between the microglobules are macropores that facilitate diffusion into the micropores.

The pore size also controls the capacity in interaction chromatography, as a result of the inverse relationship between the pore size and the interaction layer surface area, and because the interaction of biopolymers with sorbents is largely a monolayer process taking place on pore surfaces. This holds for relatively small biomacromolecules – when the size increases, pore diffusion becomes increasingly difficult and the interactions mainly take place on the perimeter of the particles, evident by a lowering of the overall loading capacity. The porous structure of the support is also related to its mechanical stability, which is important because a column with efficient separation characteristics must also withstand a substantial differential pressure. As HPLC supports are packed in closed columns, the material should have a minimal tendency to compress and swell over time, and under changing buffer and solvent conditions.

The requirements outlined above are met by rigid materials (aerogels) with soft surfaces that do not cause denaturation and irreversible sorption of biomacromolecules. Unfortunately, the mechanical and chemical design parameters converge only rarely. The rational way to design a sorbent thus goes through preparation of a matrix with suitable physical characteristics, followed by outfitting its surface with an interactive layer whose characteristics are carefully designed for the targeted separation chemistry. These modifications frequently include steps leading to deactivation of the support, i.e. to elimination of groups that enable nonspecific interactions.

The principal support material in HPLC of small molecules is surface-modified porous silica gel. This material is also central as support material in HPLC of biomacromolecules, although organic polymers are rapidly gaining more ground as they facilitate the preparation of a wide variety of surface chemistries. Polymeric sorbents of sufficient mechanical strength can nowadays be prepared by the cross-linking of natural polymers, or by direct polymerization of functional and cross-linking monomers. Many cleverly designed composite materials have also been devised where the strongly sorptive silica surface is shielded by coating with organic polymers by shrink-wrapping or grafting procedures. The primary criterion for a successful surface interaction layer is that it should exhibit a reversible and predictable sorption, preferably obeying the Langmuir isotherm with the linear portion in the operational solute concentration range. It should also exhibit site homogeneity without residual strong interaction sites. Other important properties are chemical stability under the conditions encountered during their use, rapid column equilibration, and a long shelf-life.

4.1.1 Soft Gels Based on Biopolymers

Chromatographic bioseparation was for decades synonymous with soft gels operated at low linear flow velocities in cold rooms for hours or even days, producing moderate separations. The fundamental limitation of soft xerogels is their compressibility, which prevents the use of particles smaller than about 50 µm and limits the linear flow velocity to about 1 cm min\(^{-1}\). The advent of HPLC with rigid particles capable of being pumped at flow velocities an order of magnitude faster than soft gels has revolutionized bioseparations. However, soft gels are still important in large-scale industrial biopolymer separations, and as interaction layers on rigid sorbents.

4.1.1.1 Cellulose

Cellulose is an essentially linear polymer of 1,4-\(\beta\)-glucoside-linked D-glucose, whose insolubility in water and common solvents, in combination with low nonspecific interactions, makes it well suited as a stationary phase in LC, in particular in bioaffinity schemes. It is available in native microcrystalline form, or as macroporous particles produced by regeneration in organic solvents of cellulose that has been solubilized, e.g. as a xanthate. The glycoside bond is sensitive to hydrolysis but cross-linking with difunctional reagents.
such as 1-chloro-2,3-epoxypropane (epichlorohydrine) renders the cellulose more resistant to chemical attack and improves its mechanical properties. Underivatized and functionalized cellulosics are available in the form of irregular particles, porous beads, and as membrane cartridges from a number of suppliers.

4.1.1.2 Dextran This material is a D-glucose polymer linked by 1,6-α-glucoside bonds, produced by fermentation of sucrose. The chains are branched by 1,2-, 1,3-, and 1,4-glucoside bonds, which effectively prevent crystallization. As opposed to cellulose, dextrans are soluble in water, and supports are made by cross-linking in suspension or by depositing layers of dextran cross-linked with difunctional reagents targeting the hydroxyl groups. Due to their hydrogel properties, cross-linked dextrans are soft and cannot be used under high flow rates. This prohibits their use in conventional HPLC columns. The principal use of dextran in biomacromolecule HPLC is therefore as surface layers on rigid gels.

4.1.1.3 Agarose Agarose is a linear polysaccharide comprised of alternating 1,3-linked β-D-galactopyranose and 1,4-linked 3,6-anhydro-α-galactopyranose. Agarose dissolves readily in hot water, from which it solidifies on cooling below about 50°C, a property that is used to prepare pellets or spherical agarose particles. These particles may subsequently be cross-linked with a difunctional reagent capable of forming hydrolytically stable covalent bridges between hydroxyl groups in different linear chains, thereby making the material insoluble. The cross-linking also improves the mechanical properties. Structures of agarose and a cross-linked dextran are shown in Figure 10.

On gelation, agarose forms an ordered three-dimensional structure with the polymer chains arranged to double helices that are ordered into fibrillar bundles by a combination of interchain hydrogen bonding and hydrophobic interactions. The result is a network of spatially segregated polymer aggregates, intersected by channels filled with water occupying as much as 100 times more volume than the polymer itself. These interaggregate pores provide a passage for diffusion of macromolecules and, as the pore size is inversely proportional to the agarose concentration, exclusion limits can be conveniently varied over a wide range. The structure of agarose is visualized and compared to the structure of cross-linked dextran in Figure 11.

The main drawback of agarose is its relatively low mechanical strength. Therefore agarose has traditionally been used in the format of large particles, unable to fulfill the criteria of a high-performance technique. In recent years, development of highly cross-linked agaroses has resulted in sorbents with substantially improved

![Figure 10 Structures of polysaccharides used as chromatographic supports. The dextran structure illustrates the cross-links introduced by a bifunctional reagent, in this case 1-chloro-2,3-epoxypropane.](image)

![Figure 11 Representation of the cross-linked structures of (a) dextran and (b) agarose. The unordered dextran solution forms a random network with small pores and the polymer evenly distributed in the hydrogel, whereas the thermal gelation behavior of agarose leads to formation of an ordered network with the polymer arranged into fibrillar bundles and large through pores. Note that agarose gel aggregates may actually contain 10–10^4 helices rather than the smaller numbers shown here. (Reproduced from S. Arnott et al., J. Mol. Biol., 90, 283 (1974) by permission of Academic Press.)](image)

BIOMOLECULES ANALYSIS

mechanical strength. Particles as small as 3 µm have
been successfully produced and utilized for the separation
of biopolymers..105/ Although these materials compress
under flow, this deformation can be turned into an
advantage, as controlled compression of a packed bed
results in improved column efficiency due to reduced
interparticle diffusion paths..106/
An inherent and problematic property of biological
macromolecules as chromatographic supports is their vulnerability to break-down by biological activity. Although
some polysaccharides are subject to break-down by enzymatic action, it is particularly important to protect the
supports from becoming consumed or contaminated
by microbial activity. It is therefore necessary to add
preservatives to eluents, and in particular to the solutions used for storing columns. A suitable preservative
is 200 ppm sodium azide. This applies also to SEC
(size-exclusion chromatography) stationary phases and
other highly hydrophilic separation materials based on
biomacromolecules.

several other metal oxides and insoluble metal salts that
have been used in HPLC of biomacromolecules. Alumina
is a material with a long heritage in LC, whereas zirconia
and titania have been introduced more recently. Common
to these three oxides are their advantageous mechanical
properties and their pH-stability superior to silica, which
may be useful in affinity separations..123/ However, their
high coordination numbers result in strong complexing
abilities of their surfaces and tendencies to enter ligand
exchange and ion-exchange reactions..115,124/ The Lewis
acidity and basicity are generally also higher than those
of silica, and titania has the highest Brönsted acidity of all
oxides..115/ Lewis acidity leads to strong interactions with
Lewis basic (electron donor) groups such as carboxylates
and amines, unless the surface is deactivated. Among
the nonsilica supports, zirconia seems to be the most
promising, as it is stable to the entire pH range and
amenable to facile surface functionalization..119/

4.1.2 Inorganic Oxides and Phosphates

Important factors contributing to the popularity of porous
silica, in spite of the severe pH limitations, has been
an excellent mechanical stability, good availability of
spherical particles with well defined pore size and surface
area, and the wealth of functionalization reactions that
can be carried out on the surface silanols through
formation of reasonably stable silyl ethers.
Silica is an amorphous hydrated silicon dioxide aerogel
with the formula SiO2 Ð xH2 O. Preparation takes place
through a sol-gel process where primary particles are
coalesced into spherical clusters that are subsequently
sintered and calcinated. This process renders a spherical
micro- and mesoporous structure of high fractal dimension. After rehydration the surface contains hydroxyl
groups of varying activity, in addition to siloxane bonds
between adjacent silicon atoms. The surface of a hydrated
silica has a weak Brönsted acidity due to dissociation of
free silanol groups. In undissociated form, these silanols
represent hydrogen donor groups, whereas closely spaced
surface silanols associated by hydrogen bonding offer
weak hydrogen-acceptor sites. These sites are depicted in
Figure 12.
The relative abundance of these groups on the surface
of silica is dependent on the calcination process and
the degree of subsequent hydrolysis. The acidic silanols
that are always present on hydrated silica surfaces
dissociate to a net negative charge above the pH of the
isoelectric point (pI), which is approximately at pH 3.
The calcination process also brings out Lewis acidic
and base groups onto the surface..115/ These active sites
can cause nonspecific interactions with biopolymers and
denaturation of proteins. The structural features of the
silica supports are of critical importance in separation

The inorganic materials that have found use as HPLC
stationary phases are crystalline or amorphous oxides or
phosphates of metals or semimetals. Although crystalline
materials possess a more predictable bulk and surface
structure, they are often difficult to functionalize and
their porous properties are hard to fine control. A critical
parameter is also their total insolubility in the mobile
phase, to prevent deterioration of separation properties
and depletion of the packing material. The dissolution
rate is a material property that depends on chemical
factors, such as pH and presence of chelating agents and
ions capable of dissolving the matrix or stripping the
surface functionalities off the mobile phase. Temperature
also has a substantial influence on the solubility (and
thereby stability) of chromatographic matrices.
The surfaces of inorganic oxides typically used as supports carry ionic charges of varying density, which may
exert Coulombic interactions with oppositely charged
functional groups of solutes..89/ This material property is
unpredictable and difficult to control, and is a function of
the preparation procedure and the history of the sorbent,
as well as mobile phase composition, in particular the pH.
Shielding of the active groups located on the surface by
functionalization or coating is therefore often necessary
for obtaining reproducible results. The use of inorganic
packing materials without surface functionalization is
uncommon in bioseparation. An exception is hydroxyapatite and related materials..107/ The most common
inorganic materials used as supports are listed in Table 2.
Although amorphous silicon dioxide (silica) occupies
a unique position among the inorganic oxides, there are

4.1.3 Porous Silica


Pore sizes up to 4000 Å.

Biomacromolecules are marketed in different nominal sizes, and materials for separation of large molecules, and materials for separation of biomacromolecules are marketed in different nominal pore sizes up to 4000 Å.

### Table 2: The most important insoluble inorganic materials used as HPLC supports

<table>
<thead>
<tr>
<th>Oxide</th>
<th>Application areas</th>
<th>Advantages</th>
<th>Drawbacks</th>
</tr>
</thead>
<tbody>
<tr>
<td>Silicon dioxide (silica)</td>
<td>Ubiquitous in HPLC as nonfunctionalized, surface functionalized, or polymer-coated spherical particles.</td>
<td>Available in a wide variety of pore sizes, particle diameters, and continuous beds. Commercially available in a wide range of functionalizations from highly polar to highly hydrophobic.</td>
<td>Limited pH stability (2–8), although recently launched phases are more stable towards bases. Solubility of silica increases with temperature, limiting its use at high temperatures.</td>
</tr>
<tr>
<td>Aluminum oxide (alumina)</td>
<td>Useful for the separation of biomacromolecules only after a suitable coating.</td>
<td>Better pH stability (2–12) compared to silica.</td>
<td>Strongly adsorptive Lewis acid sites must be coated for use with biomacromolecules. Cannot be modified by silanization and is therefore difficult to functionalize.</td>
</tr>
<tr>
<td>Titanium dioxide (titania)</td>
<td>Has a special affinity for organophosphates and is therefore useful for the separation of nucleotides.</td>
<td>Stable between pH 1 and 14 and amenable to functionalization by silylation. C18-modified RP titania is more stable than silica.</td>
<td>Strong Lewis and Brønsted acidity; strong Lewis basicity. Unfunctionalized titania behaves as an amphoteric ion exchanger. Limited availability of functional groups.</td>
</tr>
<tr>
<td>Zirconium dioxide (zirconia)</td>
<td>Modified with ion-exchange groups for the separation of proteins, peptides and polynucleotides. Coated with nonpolar polymers for RPHPLC.</td>
<td>Stable between pH 1 and 14.</td>
<td>Interacts with Lewis bases on solutes due to its Lewis acidity. Phosphates lower this tendency. Limited availability compared to silica.</td>
</tr>
<tr>
<td>Hydroxyapatite</td>
<td>Steric and amphiphilic ionic interactions.</td>
<td>Unique selectivity often capable of resolving subtly different proteins co-eluted in other modes. Nondenaturing elution conditions.</td>
<td>Relatively high solubility.</td>
</tr>

4.1.4 Supports Based on Semirigid Synthetic Polymeric Materials

Separation media based on polymers are currently dominating size exclusion, ion-exchange, hydrophobic interaction, and affinity chromatography of biopolymers. Numerous monomer systems are utilized, with the more important ones being styrene–divinylbenzene, and acrylic or methacrylic acids esters or amides with hydrophilic, functional, or reactive functionalities. Other examples of monomers used for the preparation of chromatographic packings are 4-vinylpyridine, 1-vinylpyrrolidinone, and vinyl acetate, the repeat units of which are partly hydrolyzed to poly(vinyl alcohol) to mention a few. The main advantage of many polymer supports is their superior stability over the entire pH range.

Most synthetic carriers have a nonionic hydrocarbon backbone characterized by hydrophobic properties. However, hydrophilic lateral functionalities in some packings, such as amide in polyacrylamide or hydroxyl groups in poly(2-hydroxyethyl methacrylate), do not allow the biomacromolecules to reach the hydrophobic main chain.
In other polymers, the hydrophobicity can be mediated through surface functionalization or coating.

### 4.2 Polymer-coated Materials

The potential inherent in coating a rigid support with a thin polymeric layer of suitable interaction characteristics was mentioned above. Polybutadiene (PBD) is often employed as a nonpolar polymeric coating on alumina, zirconia, and nonporous silica. The cross-linked PBD chains lack labile groups and provide a hydrophobic layer which is stable over the entire aqueous pH range. It can therefore be used to take advantage of the wide operational pH range of alumina and, in particular, zirconia. For example, PBD remains unaffected even by 1 M methanolic NaOH at high temperatures, a feature valuable in processes that require frequent sanitation. A problem with polymeric coatings is that the polymer layer affects the pore-size distribution of the support. For example, Reeder et al. found that PBD coated on zirconia was preferentially located in the smaller pores, which also shows up in increased mass transfer resistance as the coating thickness is increased. Several studies have furthermore shown that coated zirconia often exposes patches of the bare surface, the combination of the high hydrophobicity of PBD and the strong Lewis acid properties of the uncoated surface patches yields strong interactions and irreversible adsorption of proteins. However, these effects are mitigated if anions capable of forming strong complexes with zirconium ion, such as fluoride and phosphate, are added to the eluent. For example, phosphate-treated coated zirconia is a sorbent with both RP and cation-exchange characteristics, useful in mixed mode separations.

Poly(ethylene imine) (PEI) is another widely used coating useful for the preparation of packings for biopolymer separations. The polyimine is conveniently attached by electrostatic interaction with the acidic silanol groups of silica and cross-linked by reaction of the amino groups with bifunctional electrophilic reagents such as bisepoxides. The PEI itself has weak anion exchange properties, but reactions targeting the amine groups can be used to afford other functionalities such as cation-exchange and hydrophobic moieties. This provides for an efficient way of making mixed-mode materials. Zirconia is also a suitable substrate for PEI coating. Quaternized imino groups on PEI-coated zirconia have been used for the separation of oligonucleotides and oligodeoxynucleotides. Separation of proteins has been demonstrated on a PEI-coated zirconia converted into a weak cation exchanger by cross-linking with poly(acrylic anhydride) or succinic anhydride similar to reactions on silica, yielding carboxylic functionalities.

A poly(vinylpyrrolidinone)-coated silica was prepared by Köhler as a polar stationary phase for both normal and RPHPLC. Its hydrophobicity and advantageous mechanical properties are also suitable for the separation of biomolecules by size exclusion and hydrophobic interaction. Strong anion exchange coatings prepared by cross-linking and quaternization of poly(vinylimidazole) layers on underivatized or diol silica affords packings for protein separation. Cation-exchange coatings based on poly(aspartic acid) have been around since the early 1980s. The coating is accomplished by reacting aminopropyl silica with poly(succinimide) leading to ring opening, accompanied by a condensation to form an...
A grafting reaction has technically speaking taken place whenever a polymeric layer is covalently attached to a sorbent. A clear distinction between grafted layers and surface functionalized materials is therefore difficult to draw. To illustrate this point, the C\textsubscript{18} functionality is, in a strict sense, as much grafted layer (an ethylene nonamer graft-to) as the polyethyleneimine and polysuccinimide layers mentioned above, and the Ce\textsuperscript{4+}-initiated tentacle chains\textsuperscript{(163)} that have been brought to market in later years. It is quite clear that linear grafts can best produce the quite unique interaction layer properties characteristic of polymers, exemplified by thermally responsive separation materials (see below), but the absence of cross-linking is also accountable for the impractical chain collapse that occurs when linear alkyl phases are used in highly polar solvents.\textsuperscript{(164)}

4.3 The Biocompatibility Issue

In view of the strongly sorptive properties of biopolymers, measures must be taken to avoid unintentional interaction of solutes with surfaces other than the stationary phase, in particular in trace analytical work. A consideration when a separation system is assembled is that many proteins interact with metal ions. For instance, stainless steel frits have been identified as a major source of iron contamination in HPLC eluents.\textsuperscript{(165)} Oxidized metal surfaces (notably iron oxide) are usually Lewis acids, interacting strongly with electron-rich structures such as amines, which can have a negative influence on the chromatographic efficiency.\textsuperscript{(166)} These interactions are significantly reduced when the column frits are replaced by stainless steel meshes, demonstrating that the porous surface of the frit cannot be ignored as a contributor to the overall retention characteristics of the column. Up to a third of the protein injected on an HPLC column in microgram quantities can be trapped on the frit\textsuperscript{(167)} and the loss mechanism varies for different proteins.\textsuperscript{(168)}

Uncertainty notwithstanding, most instrument manufacturers have moved away from stainless steel as a material for construction of bioseparation systems.
Titanium was used as an alternative for a time, but seems to be largely abandoned. A report stated that the metal was not of sufficient purity or inert enough to be used in biochromatography and recommended a completely metal-free system to be used instead.\textsuperscript{172} If a metal system is used, then special concern should be given to groups with pronounced capabilities of binding to transition metal ions, such as phosphate. Provided mass spectrometry (MS) is not used in the detection step, HPLC methods for nucleotide analysis should therefore include phosphate as part of the buffer composition to saturate the binding sites on the metal surfaces.

Among the new materials which have been introduced as alternatives to stainless steel and a gained wide acceptance is poly(ether-ether-ketone) (PEEK), an aromatic polymer that owes its mechanical strength and iner-ness to its high crystallinity. Judging from its use as a material for capillary electrophoresis (CE) separation of peptides,\textsuperscript{173} and its superiority over fused silica as transfer lines in MS,\textsuperscript{174} PEEK features a low adsorption power for proteins. Extraction of PEEK parts may be necessary in order to remove metal impurities.\textsuperscript{165} However, even PEEK may exhibit problems with adsorption, as observed for instance during loop injection of nonsteroid anti-inflammatory drugs.\textsuperscript{175} In our experience, the material also suffers from fatigue after prolonged use with eluents containing high concentrations of acetonitrile, eventually leading to bursts. This may have prompted the recent introduction of gold-coated columns as a way of fighting protein adsorption.\textsuperscript{176}

Whether biocompatible or not, most HPLC columns tend to adsorb small quantities of proteins in an irreversible and/or nonspecific way, and it is often recommended that an inexpensive protein is injected a few times until the integral of the detector signal remains constant before dilute or precious samples are run on a new column.

5 SEPARATION CHEMISTRIES APPLICABLE TO HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY OF BIOMOLECULES

The range of mechanisms applicable to the separation of biological macromolecules is vast and a wide range of separation chemistries has been developed exploiting fundamental properties of molecules and separation materials. Examples are hydrodynamic radius versus pore size, hydrophilic and hydrophobic properties, ionic attraction and repulsion, and specific interactions of solutes with immobilized functional entities of synthetic or biological origin. Chemistries are chosen in the context of the overall purpose of the separation work, and the isolation of biological macromolecules from crude biological feedstock does almost invariably require several cleaning steps for work-up and final polishing, regardless of whether the purpose of the overall separation scheme is analytical or preparative. As many biological macromolecules are sensitive to denaturation at phase boundaries and on contact with xenobiotic surfaces, the separation process itself may induce serious breakdown of fragile biomolecules. Loss of substance and/or biological activity can thus occur in each separation step, and also during handling of the solutions. Therefore, the overall separation process should be optimized to involve a minimum number of steps required to achieve the desired separation. Separation techniques are therefore preferably chosen so that fractions collected from early separations can be applied to the next separation column without excessive sample handling. A key to success is orthogonal selectivities, i.e. careful selection of a set of techniques where the mechanisms exploited in each step are complementary, so that the separation can be maximized in the minimum number of separations.

Obviously, high-performance techniques make this goal easier to achieve because the efficiency in each step is higher compared to open column separations. The high efficiency enables minimization of the cycle time in each separation and a considerable increase in the total throughput. Rapid separation has a positive effect on the yield and purity of the substances separated, as denaturation due to contact with sorbents and other surfaces in the separation equipment is time-dependent.

5.1 Size-exclusion Chromatography

SEC is the common name for the liquid chromatographic modes where molecules are separated on the basis of steric exclusion from the dimensional parameters of a well-defined gel or a pore network. The stationary phases are commonly referred to as gels, but bimodal porous materials are also often used in SEC. Separation is achieved as molecules of different sizes are either being allowed to penetrate or are excluded from the pores within the packing, depending on their hydrodynamic radius. Large molecules that cannot enter the pores are eluted in the interstitial void volume of the column $V_0$, whereas small molecules capable of freely diffusing into the solvent imbibed by the pore system are retarded and elute when the entire solvent volume of the column $V_1$ has passed. The actual stationary phase is in this specific case the stagnant mobile phase.

Molecules of intermediate size are partly excluded and are fractionated based on their relative size (actually hydrodynamic radii) and eluted between $V_0$ and $V_1$ in
order of decreasing molecular weight (Figure 14). SEC is the only separation mode in LC (except slalom chromatography, see below) where enthalpic contributions are intended to be absent from the retention mechanism. It is consequently a process driven by differences in entropy, and is characterized as a noninteractive chromatographic mode.

Under equilibrium conditions, the partition coefficient \( K_D \), which is independent of column dimension, is defined for a molecule eluting at a specific volume \( V_e \) between \( V_0 \) and \( V_1 \) by Equation (21):

\[
K_D = \frac{V_e - V_0}{V_1 - V_0}
\]

This partition coefficient will always have a value between 0 and 1, and is dependent on the pore-size distribution of the stationary phase, and on the size and shape of the macromolecular solute.

As opposed to many other macromolecules, water-soluble proteins in their native state are folded into compact, globular entities, enabling the use of aqueous SEC for estimating their molecular size if SEC columns are calibrated by plotting log(molecular weight) of a set of protein standards against \( K_D \). What must be realized is that this procedure does not measure the molecular weight, but rather the hydrodynamic size of the proteins, as demonstrated by Figure 15. The graph shown is taken from a study by le Maire et al.,(178) where a number of water-soluble globular proteins and detergent-soluble membrane proteins of determined Stokes radii were used to establish SEC calibration curves. Several of the proteins in Figure 15 fall outside the calibration curve based on molecular weight, and the two groups of protein tested behaved differently and should therefore be calibrated with different sets of standards.(178)

The anomalies in Figure 15 are caused by deviation from spherical shape. The size of a protein can be determined by analytical ultracentrifugation(179) or by measurement of its diffusion coefficient \( D_p \), and is expressed by the Stokes radius \( R_S \), which is the size of spherical particle that would have the same frictional coefficient \( f_p \) as the protein:

\[
f_p = \frac{RT}{ND_p} = 6\pi\eta_0R_S
\]

Using Equation (22), \( R_S \) can be calculated from \( f_p \) when the viscosity of the solvent \( \eta_0 \) is known.

However, because proteins deviate from sphericity and carry a certain amount of attached and encapsulated water, their actual frictional coefficients or Stokes radii are usually larger than would be the size of a perfect globule, \( R_{\text{min}} \). Typical values of \( R_S/R_{\text{min}} \) for globular proteins are of the order of 1.2 but, due to asymmetrical shape, the actual size along the longest dimension can be substantially larger. Of the proteins deviating from the calibration curve in Figure 15(a), BSA has an \( R_S/R_{\text{min}} \) of 1.35, whereas the value for tyrosyl-tRNA synthase is 1.48. The anomalous retention behavior of fibrinogen is explained by its elongated, fibrillar shape, which prevents it from being characterized by a simple size parameter. An alternative for such molecules is a universal calibration based on intrinsic viscosimetric radii obtained from measurements of mass \( M \) and intrinsic viscosity \( \eta^* \)(180) (Equation 23):

\[
R_\eta = \left( \frac{3[n]M}{10\pi N_a} \right)^{1/3}
\]

where \( N_a \) is Avogadro’s number. A detailed account of universal calibration for SEC(180–186) is beyond the scope of this article. The conclusion here is that aqueous SEC is capable of measuring the hydrodynamic size of biopolymers, but that this size cannot be directly translated into molecular weight.

To ascertain a predictable separation based on molecular size, i.e. to ensure that sieving is the sole mechanism governing the separation, intermolecular forces acting between the solute and the mobile phase have to be
Figure 15 Calibration curves for some water-soluble proteins and solubilized membrane proteins on a TSK 3000SW SEC column based on (a) log(MW) and frictional coefficient based on (b) Stokes radii as size parameters. The improved fit by calibrating against frictional coefficient-based Stokes radius is due to deviation from sphericity. Fibrinogen has a very asymmetric shape and was excluded from the calibration. Bacteriorhodopsin, which also deviates from the calibration curve, binds a large amount of solubilizing detergent. (Reproduced from M. le Maire et al., Anal. Biochem., 154, 525–535 (1986) by permission of Academic Press.)

substantially stronger than the interactions between the solute and the stationary phase. This means that all partitioning reaction equilibrium constants should be as close to zero as possible. All solutes then elute in a defined retention range, the retention window. This window extends from the interstitial void volume of the packed bed ($V_0$; totally excluded large molecules) to the total solvent volume in the column ($V_t$; small solutes capable of penetrating all the pores; Figure 15). A peculiarity of SEC is consequently that all solutes have negative or zero capacity factors $k'$ if the void volume is measured by conventional methods.

5.1.1 Stationary Phases for Size-exclusion Chromatography

When SEC is applied to the separation of biomacromolecules, aqueous buffers are utilized as mobile phases. Aqueous SEC is sometimes referred to as gel filtration chromatography, in particular by biochemists, but this term should be reserved for the low-pressure open-column variant. Columns for high-performance aqueous SEC, based on native or modified silica, hydrophilic synthetic polymers with well defined pore size, or cross-linked polysaccharides, are available from numerous manufacturers. A separation medium having pores of a specific size distribution is chosen to cover the molecular weight range required for the actual separation.

As SEC separations are based on size, it is an inherently generic concept for separation of macromolecular compounds. However, it suffers from rather low separation efficiency, resulting from the narrow separation window which dictates that all solutes should (ideally) elute within a very limited retention time-frame. In preparative SEC separations the limited resolution is dealt with by selecting a gel with suitable molecular size separation range, so that the solutes of interest fall within the range of maximum separation efficiency (typically around $K_D = 0.5$), whereas both larger and smaller molecules are eluted ahead of (close to $V_0$) or after the desired molecular size range (near $V_t$).

Although modern SEC stationary phases are designed to minimize partition interactions and serve only as a gateway allowing or denying access to the liquid phase trapped in its internal network,\(^{187,188}\) most phases still have a low residual negative charge due to carboxylic groups or dissociated silica. These residual charges give rise to unintentional partition interactions,\(^{189}\) and have in fact even enabled comparisons of ion-exchange interaction models to be carried out on SEC stationary phases.\(^{189}\) Although ionic interactions are generally unwanted, they can be utilized for mixed-mode SEC separations involving an ion-exchange component.\(^{190}\)

When silica is used as a separation material in SEC, the charges from dissociated silanols should be shielded...
from interacting with the solutes. One way to compensate for the negative charge of silica is to use a shielding layer with a low positive charge.\(^{[6]}\) Furthermore, although highly hydrophilic materials are typically used, the risk of weak hydrophobic interactions cannot be ruled out in fully aqueous media.

### 5.1.2 Applications and Practical Considerations

Gradient elution is not applicable to SEC, because the partition interaction variations that gradients are meant to develop would obviate the separation principle. As isocratic separations are dependent on the column efficiency, high-performance size-exclusion chromatography (HPSEC) columns are typically long and narrow and used at quite low linear flow rates, in contrast to columns used in interaction-based separation techniques. Selection of column and operating conditions is dependent on the application and the resolution required. The column packing should be selected so that all solutes of interest fall within the molecular weight fractionation range of the gel, as specified by the manufacturer. Separation of molecules with large differences in molecular size can thereby only be obtained if the separation material has a relatively wide span in pore sizes. However, this means that the separation power in the retention window becomes relatively poor and when the span in solute molecular weights is large, which often applies to carbohydrate polymers, a preferred alternative is to use several columns with different and more narrow molecular weight separation ranges in series.\(^{[191,192]}\)

For instance, four connected HPSEC columns have been used to characterize starch-based carbohydrates.\(^{[193]}\) Also, three series-coupled columns were used in combination with differential refractive index (RI) and viscometry to separate and determine the shapes and aggregation states of complex plant cell-wall polysaccharides,\(^{[194]}\) of amylopectin and amylose in microwave hydrolyzed starch,\(^{[195]}\) and together with multiple angle laser light scattering (MALLS) detection for characterizing and obtaining information on the solution behavior of carbohydrate biological response modifiers\(^{[196]}\) (Figure 16).

Coupled-column HPSEC is also used for studying protein aggregation, for instance, to determine toxic high-molecular-weight components present in therapeutic-grade glutaraldehyde-cross-linked polyhemoglobin,\(^{[197]}\) and aggregates formed in heat-treated bovine \(\beta\)-lactoglobulin.\(^{[198]}\) More commonplace separations are carried out on single columns, such as molecular weight determination of proteins, nucleic acid, plasmids, and less complex polysaccharides. Columns with a selectivity in the lower end of the molecular weight scale have also recently been marketed, providing good resolution of peptides. Among the more interesting of current developments are investigations of temperature-responsive materials as SEC stationary phases.\(^{[199]}\) Apart from its use in preparative and analytical separations, aqueous SEC is also frequently used as a unit operation to accomplish desalting and buffer exchange in intermediate sample preparation steps.

The choice of eluent is relatively open, as long as sufficient salt is present to cancel ionic interactions, and the salt concentration does not exceed the level where proteins start to precipitate, or hydrophobic interactions (see below) come into play. Sodium chloride is the most commonly used salt at 0.1–0.3 M concentration, with pH being controlled by a suitable buffer with solution-phase interactions taken into account. The solute stability rather than the separation chemistry thus governs the mobile phase composition, which adds to the notion of SEC as being a very mild technique.

---

**Figure 16** Molecular mass versus elution volume and concentration versus elution volume chromatograms for carbohydrate biological response modifiers, as established by SEC with MALLS and differential viscosity detection. Schizophyllan and glucan phosphate were analyzed by argon ion (488 nm) MALLS. Krestin was analyzed by helium–neon (633 nm) MALLS because of significant fluorescence at 488 nm. The Gaussian curves represent the concentration chromatograms, whereas the linear relationships represent the molecular mass versus elution volume chromatograms. (Reproduced from A. Müller et al., *J. Chromatogr. B*, 666, 286 (1995) by permission of Elsevier Science B.V.)
Sample loading on SEC columns requires some consideration. As in all elution HPLC techniques, the sample is applied in a finite volume on the column head. However, in contrast to most other biomacromolecule separation chemistries, which can tolerate relatively large sample volumes as long as they are loaded from solutions with weak elution power due to the stop-and-go control in gradient elution, there is generally no weak eluent at hand in SEC to accomplish a band sharpening at the column head. The sample loading capacity of SEC is inherently high because the total volume of the gel is used in the separation process but, in order to minimize band broadening, it is critical to keep the sample size low, or to use a sample preconcentration technique of some sort such as the online isotachophoretic technique described by Öfverstedt and Eriksson. The sample should furthermore have a viscosity that is similar to that of the eluent.

Separation along basically the same selectivity dimension as SEC can be accomplished in SDS/PAGE with better resolution, wider molecular size window, and more degrees of freedom in the selection of operational parameters. The SDS/PAGE technique is also used regularly for checking fractions eluted in SEC. The advantage of SEC over its electrophoretic counterpart lies in its soft separation process but, in order to minimize band broadening, it is critical to keep the sample size low, or to use a sample preconcentration technique of some sort such as the online isotachophoretic technique described by Öfverstedt and Eriksson. The sample should furthermore have a viscosity that is similar to that of the eluent.

Summing up, the genuine value of SEC as an HPLC technique lies in its separation dimension, which is often complementary to other separation chemistries. In spite of its comparatively low resolution, SEC is therefore often employed in combination with other, more powerful HPLC techniques, where SEC usually is applied as the first of several chromatographic steps. In general, fractions from aqueous SEC can be applied directly to RP separations, or to IEC or HIC (see below) after dilution to lower the salt strength, or after addition of salt, respectively. Several monographs have been published over the last years dealing entirely or mainly with SEC. The book edited by Wu contains information on commercial separation materials, both from the manufacturer and user viewpoints.

5.2 Normal-phase Liquid Chromatography

LC on polar supports using less-polar solvents as eluents was the original mode used in ancient column chromatography by Tswett, hence the term “normal phase” (NP), sometimes also “straight phase”. Today, normal-phase high-performance liquid chromatography (NP-HPLC) does not live up to its name and is among the less frequently used separation techniques in analytical chromatography. Because of the nonpolar solvents, and the high and often unpredictable retention of traditional inorganic oxide stationary phases towards polar functional groups, NP chromatography on conventional inorganic materials has been of limited use for biomacromolecules. The exception is peptides, for which several workers have demonstrated its utility.

Lerro et al. used an aminopropylsilica column with an isopropylamine-modified chloroform–methanol gradient eluent to separate sticky amphiphilic synthetic peptides that were unresolvable by other methods. The peptides were separated on the basis of chain length, with recoveries better than 90%. Yoshida recently demonstrated that columns with amide functionality (carbamoyl silica) are useful for peptide separation in NP mode with a gradient of aqueous acetonitrile containing 0.1% trifluoroacetic acid (TFA). These eluent conditions resemble those used for RP-HPLC of peptides, but with a reversed gradient and a distinctly polar separation material. Hydrophilic peptides that were unretracted in the RP mode could thus be retained and separated by NP-HPLC, and the selectivity difference in the NP and RP modes made it possible to carry outtwo-dimensional separations of a protein digest (Figure 17). The retention coefficients established by linear multiple regression analysis of retention times of a large number of peptides can be used to predict retention times of peptides of known sequence. A linear relationship has also been established between log and the logarithm of the volume fraction of mobile phase modifier, so that both isocratic and gradient retention times can be predicted after two initial gradient runs.

Separation of very short peptides in NP-HPLC has also been demonstrated recently by Armstrong et al. using silica gels modified with ristocetin or teicoplanin as chiral stationary phases (CSPs).

5.2.1 Hydrophilic Interactions Chromatography

NP chromatography has been revived in hydrophilic interaction chromatography (HILIC) which shares much the same separation principle, i.e. a stationary phase that is more polar than the mobile phase. The acronym HILIC was coined by Alpert and the main difference compared to NP-HPLC is the use of more polar and thus stronger eluents, and of columns specifically developed.
Figure 17 Complementary selectivities of RPHPLC and NPHPLC in peptide separation. (a) Chromatogram of a tryptic digest of concanavalin A on a TSK gel ODS-80Ts RP column. The digest was separated with a 90-min linear gradient of 5–55% acetonitrile in 0.1% TFA. Thirteen fractions were collected from this separation and subjected to NP separations producing the chromatograms shown in (b), eluted by 70-min linear reversed gradients of acetonitrile from 97% to 55% in 0.1% TFA. Both columns were 250 x 4.6 mm i.d. Peak identification: 1 = TAK, 2 = DQK, 3 = SK, 4 = SVR, 5 = VSSNGPEGSSVGR, 6 = VSSNGPEGSSVGR, 7 = SNSHOTDALHPFENQFSK, 8 = ETNTLSTWFSFTSK, 9 = VGTATHIYNSVDK, 10 = VGLSASTGKYK, 11 = DILILQGDTGDNGNLGR, 12 = LLGLFDPAN, 13 = ADITIVA-

for biomacromolecule separation. The packing originally devised by Alpert was a poly(succinimide)-coated silica modified by diethanolamine. More recently, materials with other functional groups have also been tested for HILIC, including a carbamoylated polymeric phase,\(^{213}\) aminopropyl-derivatized silica,\(^{214,215}\) and zirconia.\(^{216}\)

The preferred organic solvent is acetonitrile, typically at 50% or higher admixture in water, but alcohols such as 2-propanol can also be used. However, as the alcohols are rather polar, the concentration required will be higher, leading to more viscous eluents. Addition of salts to the eluent is not required for nonelectrolyte solutes, but salt should be added to reduce residual electrostatic interactions with charged solutes. Gradient elution is achieved by decreasing the concentration of the organic solvent, thus increasing the concentration of the strong eluent component which is water. An alternative way of forming the gradient is to maintain the organic solvent admixture and increase the salt concentration. For highly hydrophilic solutes, a combination gradient with decreasing organic modifier content and increasing salt concentration can be advantageous. For peptides, the retention is a function of the hydrophilicity of the lateral groups, whereby basic moieties contribute most to the retention. The selectivity is thus opposite to that seen in RPHPLC, with Asn, Ser, and Gly being strong promoters of retention, whereas Phe and Leu provide little retention. The eluent pH can be used to control the selectivity, because at low pH only basic and phosphorylated groups will be charged, whereas both acidic and basic residues will be charged at a pH close to neutral. As basic groups are strong promoters of retention, a low pH eluent will elute peptides essentially according to an increasing number of basic residues. But as opposed to cation-exchange chromatography, a highly hydrophilic peptide can be more retained than a hydrophobic peptide with more basic residues. The selectivity of HILIC is therefore complementary to cation exchange. As the organic solvent is the weaker eluent component, samples should be prepared in a solution containing at least the same concentration of organic solvent as the eluent to obtain a band sharpening at the column inlet.\(^{217}\) A separation using a polymeric HILIC column is shown in Figure 18.

The HILIC technique is particularly useful for the separations of biological macromolecules with pronounced capabilities of expressing hydrophilic interactions that are stable to the mostly organic eluents used. Compounds
5.3 Separation Modes Based on Hydrophobic Interactions

RPHPLC is the most common separation technique for small organic compounds. The separation is characterized by the use of hydrophobic stationary phases in combination with relatively polar mobile phases, typically comprising mixtures of water-miscible organic solvents and water. A common misconception is that transfer of solutes between the mobile phase and the interaction layer is driven by interactive forces occurring mainly in the hydrophobic stationary phase. In reality, however, the retention process is largely driven by solvophobic forces, where the transfer of a solute to the stationary phase is effected by solvophobic expulsion from its cavity in the mobile phase, accompanied by displacement of eluent components from the stationary phase and release of solvent from the solute. The reverse process involves creation of a cavity in the solvent, solvation of the solute, and reoccupation of stationary phase surface by components of the eluent. The selectivity is easily modulated by solute dissociation or ion-pair formation, widening the scope of this versatile stationary phase–solvent system. In addition to the eluent, altering and fine tuning of the selectivity can be achieved through the choice of a specific column from a wide variety of commercially available stationary phases with alkyl chains of different lengths, and by variation of the ligand type, density, and structure. The broad range of interactions makes RPHPLC suitable for the separation of drugs and other xenobiotics, as well as low-molecular-weight compounds of biological origin.

5.3.1 Reversed-phase High-performance Liquid Chromatography of Biological Macromolecules

The ubiquitous RPHPLC stationary phase is bonded-phase silica, due to the advantageous mechanical properties and solvent resistance offered by the silica matrix, and to the variety of well-characterized chemistries available. The predominant functional groups are linear alkyl chains, in particular C₁₈ (n-octadecyl), which provides a surface with relatively strong hydrophobicity and high capacity, suitable for interaction with small molecules. Less hydrophobic ligands such as octyl (C₈), butyl (C₄), phenyl, and cyanopropyl are also used, as are polymer-coated columns. The nature of the functional groups plays an important role in the retention, and the factors that appear to affect the interactive process are hydrophobicity, flexibility, and the degree to which surface silanols are exposed in the contact surface.

The versatility of RPHPLC is further derived from the large span in eluting powers offered by solvents such as alcohols, acetonitrile, and some ethers. These solvents can be used in combination with water to vary the retention over a very wide range, even with the same stationary phase, enabling excellent resolution of similar and structurally disparate substances. The preferred solvent is often acetonitrile because of the low viscosity and good UV transparency of its mixtures.
with water. As the fraction of water in the eluents is relatively large, it is also possible to use conventional buffers for controlling retention. The retention can be controlled by the eluent pH to affect the degree of solute dissociation or protonation (ion suppression), or by additives such as short-chain ionic detergents, to promote the formation of hydrophobic ion pairs, which can be retained on the column.\(^{231,232}\) These eluent manipulations enable selective retention adjustment for solutes with dissociation equilibria within and beyond the somewhat limited operational pH range of bonded-phase silica columns.

Although RPHPLC has been used for isolation and analysis of proteins,\(^{99}\) it is rarely possible to recover the substances in their native or active state due to their interactions with the highly hydrophobic surfaces of conventional RPHPLC materials, and the denaturation power of the eluents. The retention process can also result in substantial loss of proteins that become tightly trapped on the separation material, apparently via hydrophobic domains existing in continuous regions on the surfaces of the protein.\(^{233}\) The recovery of proteins depends largely on chain length of the hydrophobic ligand, with shorter ligands usually affording better yields and conformational integrity. Butyl and cyanopropyl silica are therefore preferred over longer alkyl chains and phenyl groups. The main application of RPHPLC in biopolymer separation is for natural, enzymatically derived, and synthetic peptides.\(^{99,234–239}\) It has been found empirically that the retention factor of peptides eluted under linear sorption conditions can be expressed as a function of the mole fraction \(\varphi\) of the organic eluent component according to Equation (24),

\[
\log k = \log k_{0,\text{RP}}^c - S\varphi
\]

where \(S\) is the slope of the plot \(\log k'\) versus \(\varphi\), and \(\log k_{0}^c\) is the intercept, i.e. the extrapolated \(k'\) for hypothetical separation with no organic modifier added.\(^{99}\) The dependency of \(k'\) on \(\varphi\) is affected by temperature and eluent pH and may have different shapes (see Figure 46). As a result of multiple contact point interactions, the values of \(S\) and \(\log k_{0,\text{RP}}\) are usually larger for biomacromolecules than for small molecules, requiring the use of gradients to elute different biomacromolecules within a single run.

Separation in RPHPLC results from differences in the intrinsic hydrophobicity of the solutes, the eluotropic properties of the mobile phase, and the hydrophobic properties of the packing. The kinetics and strength of the interaction are determined by the number and type of exposed groups of the peptide and their spatial arrangement, as proteinaceous materials are known to interact with surfaces in an orientation-specific manner. Using cytochrome \(c\) and bovine growth hormone as model proteins, it was recently verified that the contact areas are localized on the protein surfaces and that the proteins retain their three-dimensional shape when attached to an RP sorbent.\(^{233}\) For a sizable molecule such as a protein, the contact functionalities are thus usually those exposed at the protein surface, whereas most of the amino acid residues can take part in the retentive process that involves small peptides. Therefore retention of peptides that have not assumed a secondary structure can be predicted with reasonable accuracy.\(^{240}\)

Acidic mobile phases are typically used for the separation of proteins and peptides in RPHPLC. This ensures that the surface silanols of the stationary phase are protonated, thus minimizing undesired ionic interactions with basic amino acid residues. The pH value is adjusted by adding about 0.1% of an acid such as TFA, heptfluorobutyric acid (HFBA), \(\text{H}_3\text{PO}_4\), \(\text{HClO}_4\), or \(\text{HCl}\), with the choice of acid based on the detection mode and selectivity.\(^{241}\) The volatile perfluorocarboxylic acids (TFA and HFBA) are advantageous for LC coupled to MS where the acid must not interfere with the ionization process. Hydrochloric acid has corrosive properties, which makes the use of inert systems mandatory. The acid anion also serves as an ion-pairing agent for the basic amino acid residues, implying that the separation selectivity can be altered by choosing acids with anions of suitable hydrophobicity. For example, HFBA increases the retention relative to TFA, whereas phosphoric acid renders the ion pairs more hydrophilic and lowers the retention. The perchlorate ion has chaotic properties that increase the hydrophobicity of the peptides by forming ion pairs with basic residues\(^{236}\) (Figure 19).

Many amphiphilic biopolymers, notably membrane proteins and peptides with long hydrophobic segments, require additional eluent components such as nonionic detergents to prevent the solutes from irreversible precipitation in the hydrophobic column.\(^{99,242}\) However, if the solutes call for such measures in RPHPLC, it might be better to investigate other separation modes. Scaling up RPHPLC separations is relatively simple, and crude synthetic peptides are often separated on analytical columns to develop preparative HPLC procedures for product clean-up, followed by analysis of aliquots of purified material with a different eluent composition or another separation chemistry.\(^{99}\)

### 5.3.2 Hydrophobic Interaction Chromatography

This is a variant of RP chromatography suitable for separation of proteins with maintained biological activity.\(^{227,243–247}\) The concept was first described in the late 1940s as salting-out chromatography\(^{248,249}\) and has
its roots in protein chemistry. Whereas organic solvents are needed to break the strong hydrophobic interactions in RPHPLC, HIC benefits from being carried out in completely aqueous eluents. Columns used in HIC are only moderately hydrophobic, and retention is based on the tendency of proteins to absorb on surfaces in the presence of cosmotropic salts that enable a salting out of proteins. These salts are positioned to the left in the Hofmeister series:

$$\text{SO}_4^{2-} > \text{Cl}^- > \text{Br}^- > \text{NO}_3^- > \text{ClO}_4^- > \Gamma^- > \text{SCN}^-$$

The salt cation also affects the interaction strength, although to a lower degree, according to the following:

$$\text{Mg}^{2+} > \text{Li}^+ > \text{Na}^+ > \text{K}^+ > \text{NH}_4^+$$

Retention is a function of the extent of hydrophobic interaction, and varies with both the hydrophobicity of the stationary phase and the concentration of the cosmotropic salt. The commonly used retention-promoting salts are ammonium sulfate and sodium chloride. Samples are applied to the column in a neutral pH loading buffer containing the cosmotropic salt at relatively high concentration. Elution of adsorbed proteins is achieved by a gradient of decreasing concentration of the salt, with a buffer added at a relatively low concentration to maintain the eluent pH. The features of RPHPLC and HIC are compared in Table 3.

The traditional stationary phases for HIC are soft gels, modified to increase the hydrophobicity, and used in low pressure protein chromatography. However, in recent years a number of rigid phases have become available based on silica, cross-linked agarose and synthetic polymers with a variety of functional groups including short-chain alkyl chains, phenyl groups, oligoethylene glycol and intermediately polar groups such as poly(alkylaspart-amides).

The polar–apolar characteristics of nine different RPHPLC and HIC columns were investigated by Rippel et al. using homologous series as probes. The default eluent anion is sulfate, whose solubility and salting-out effect is well known and suitable for most separations in HIC. However, selectivity is influenced by the salt type used in the inverse gradient, as well as by other additives affecting the conformation of the proteins under separation. The differences between sodium,

---

**Figure 19** Separation of model synthetic peptides in the absence and presence of 100 mM NaClO$_4$. An aquapore RP-300 C$_8$ column (220 × 4.6 mm i.d.; 7 μm; 300 Å) was used with a linear (1% acetonitrile per minute) gradient from 20 mM aqueous H$_3$PO$_4$ (pH 2.0) to 20 mM H$_3$PO$_4$ in 50% aqueous acetonitrile. Sodium perchlorate addition took place in both eluents. (Reproduced from T.J. Sereda et al., *J. Chromatogr. A*, 776, 163 (1997) by permission of Elsevier Science B.V.)
potassium, or ammonium as counterions to sulfate was studied on a phenyl column by Kato et al., who found that sodium resulted in the most efficient protein retention, and that separations could be modeled to a certain extent by interchanging sodium and ammonium sulfate. Solvents and other chaotropic agents could also be used to speed up elution and to improve resolution while maintaining the proteins in their native state. Selection of optimal conditions for the separation of proteins by ammonium sulfate gradients can be done by employing isocratic elution with different eluents or proteins by ammonium sulfate. Solvents and other chaotropic agents could also be added to the eluent.

The major drawback of HIC is the relatively high concentration of salt present in the eluted proteins. Due to the separation mechanism, proteins elute close to their critical point and are sensitive to adsorption on surfaces unless the concentration of cosmotropic salt is decreased. Desalting can be accomplished by SEC, by dialysis, or by ultrafiltration. However, none of these techniques are readily applicable to on-line detection, such as LC/MS. Buffers containing volatile salts such as ammonium acetate, ammonium carbonate, and ammonium formate are possible, and best separations have been obtained with the acetate. Addition of up to 6 M urea to an ammonium sulfate mobile phase for a silica column with ether groups has been shown to have a substantial effect on the retention of several proteins, attributed to conformational changes.

Solvophobic theory has been extended to HIC. Melander et al. found that a simple two-parameter model can be used to model the retention of proteins and peptides in linear gradient elution (decreasing salt or increasing solvent strength). Geng et al. assumed a mechanism where water is the displacing substance. By varying the pH and the concentration of a series of eluent salts on ether type columns with alcohol or increasing solvent strength. Geng et al. showed that plots of log k versus log[H₂O] for lysozyme and albumin were linear, with isotherms of a type that supported a stoichiometric displacement mechanism. Multivariate analysis was recently applied by Oscarsson and Karsnäs to study the effects of salt type and concentration on adsorption of serum protein to butyl, octyl, phenyl, and mercaptopyridine agaroses. Different adsorption mechanisms were operating depending on adsorbent and buffer conditions. Other studies of HIC interactions have found that the retention of ionizable solutes is explainable by a modified double-layer adsorption model. Apart from separation of proteins and peptides with minimal denaturation, HIC has also been used for the

![Figure 20](image-url)
separation of single stranded oligo-DNA and oligo-RNA nucleotide fragments.\(^{(275)}\)

Although HIC is generally regarded as one of the softer separation techniques, capable of preserving the separated proteins in their native state,\(^{(95)}\) problems with denaturation do occur. For example, De Frutos et al.\(^{(276)}\) reported pH-dependent formation of multiple peaks in separations of \(\beta\)-lactoglobulins on a polyether silica, which was ascribed to denaturation, dissociation, or aggregation at different pH and temperature (Figure 21). Conformationally labile proteins elute as broadened peaks\(^{(277)}\) and variations in temperature can be used to identify unfolding and assess its extent in HIC separations.\(^{(278)}\)

Sample loading can also be problematic because the HIC mechanism requires the proteins to be close to their limit of solubility. Large sample volumes can be used, provided that the salt concentration in the sample is sufficiently high\(^{(279)}\) but, for proteins of low solubility, multiple injections of sample with lower ionic strength is a better way of loading a larger sample onto the column.\(^{(252)}\) Furthermore, precipitation of solutes on the column can occur if the protein concentration is high and the buffer pH is close to the pI of the proteins. In view of the retention-promoting effect of cosmotropic salts in HIC, it is obvious that these salts should be avoided in separation modes where nonspecific hydrophobic adsorption to stationary phases is detrimental, as in SEC and HPLAC. Conversely, an advantage of the high salt loading solutions is that eluates from ion-exchange separations can be applied to HIC columns without desalting.

5.4 High-performance Liquid-affinity Chromatography

One of the characteristic features of biological macromolecules is their ability to enter highly selective and reversible interactions with other molecules. Examples of such interactions in vivo are the capture of antigens and haptens by antibodies, the attachment of substrates, inhibitors, cofactors and substrates to active sites of enzymes, binding of nucleic acids to complementary nucleotide bases, and the affinity of hormones and toxins for receptors. Such dissociable biospecific complexes form the basis for affinity chromatography and HPLAC.\(^{(56,103,280–288)}\) Affinity chromatography is defined as a binary (on–off) separation technique based on specific interactions between solutes and ligands designed for a single compound or a narrow group of biological macromolecules.

The extraordinary specificity of bioaffinity interactions makes it possible to achieve the required separations even with low-efficiency separation materials such as soft gels, albeit at a penalty of long equilibration times and low flow rates. High binding constants also enable the use of sorbent layers with exceptional structure and extreme aspect ratios such as fibrous membranes\(^{(283,289)}\) (Figure 22). Low-pressure techniques are therefore still extensively used in purification of biomolecules by affinity interactions. New high-efficiency separation materials have made HPLAC an interesting unit operation in various specific detection schemes, occupying a position between conventional separation science and dedicated immunochemical analysis methods.\(^{(290)}\)

The operating principle of bioaffinity chromatography is shown in Figure 23, and encompasses a specific interaction of the molecule to be purified with an immobilized affinity ligand, leading to an attachment of

A, 798, 71 (1998) by permission of Elsevier Science B.V.)

Figure 23 Diagram of the different steps involved in the use of bioaffinity chromatography.

the solute. The attachment step is followed by a washing step, whereby nonbonded molecules are rinsed from the column. The final step is the elution, where the selectively sequestered molecules are recovered by elution with competing substrate, or by applying conditions that lead to an altered conformation of the attached biological macromolecule that results in loss of specific interaction.

Affinity chromatography can thus be regarded more as a set of chemical operations aided by a heterogeneous surface than chromatography in a conventional sense.

Therefore, optimal conditions must be sought for each step in this procedure. The ligand is chosen on the basis of its ability to form reversible complexes with the solutes to be separated, and should have a functional group through which it is attached to a support without seriously altering its biospecific binding properties. The binding constant should be sufficiently high, and the ligand should possess a specificity adequate for the desired separation. The association and dissociation rates of the binding reaction should be fast and the binding strength controllable over a wide range by simple and non-denaturing changes of conditions, so that solutes can be eluted in sharp bands without irreversible conformational changes being imparted on the solute. Ligands for HPLAC can either be biopolymers or low-molecular-weight compounds.

The association strength between the ligand and the solute is central. If the interaction is too weak, the solute will fail to become efficiently sequestered. In contrast, if the interaction strength is too high, it will be hard to find acceptable elution conditions. The specific multipoint interactions that have to be established and dissociated often have slower kinetics than more general interactions with less heterogeneous interaction layers.

5.4.1 Stationary Phases for High-performance Liquid-affinity Chromatography

The traditional bioaffinity supports have been soft hydrophilic gels, mainly cross-linked agarose, and the activation required to covalently immobilize the ligand has often been done by the user. In later years, a variety of pre-activated matrices have emerged, many of them based on alternative materials such as synthetic hydrophilic polymers and inorganic oxides. Rigid supports have enabled the evolution of bioaffinity chromatography into a much faster high performance technique.

The properties of the solid support matrix are very important in bioaffinity chromatography because they affect the stability of the immobilized ligand. Correct choice of matrix is thus essential for successful separation.
Porath has pointed out the following properties for a suitable bioaffinity chromatography support:\(^{(291)}\)

- insolubility;
- a large specific area with sufficient permeability in particles of suitable rigidity and suitable form;
- the absence of native sorption capacity, which translates into a hydrophilic character;
- a chemical reactivity sufficient to allow introduction of affinity ligands;
- a chemical stability under the conditions required for the attachment, adsorption, desorption, and regeneration, including resistance towards microbial and enzymatic attacks.

The size and accessibility of the pores are particularly important, as the porous system should be spacious enough to accommodate both the ligand and the target molecule, and to allow the biospecific interaction to occur undisturbed. Yet to maintain a reasonable capacity, the pore size should not be too large because of its inverse relationship with surface area. A network of evenly sized pores of the correct dimension is therefore required to obtain optimal kinetics and capacity. The surface properties of the pore system are also a key factor. During use, solutes should ideally form complexes only with the bonded affinant and exhibit minimal interaction with the support matrix. Because of the amphiphilic properties of biomacromolecules (which are advantageously used in HIC), a highly hydrophilic support is needed to diminish nonspecific interactions. For the same reason, ionic or ionogenic supports are seldom used. Because of this sensitivity to the nature of the support and the immobilization chemistry, several different matrices should be evaluated when HPLAC methods are developed.

Strong linkage of the affinant to the support is also very important. The support must therefore carry active groups, or groups capable of being activated to enable a stable and irreversible attachment. A large variety of immobilization chemistries have been developed, facilitating the attachment of various affinants. As the desired adsorption and desorption of solutes requires eluents with different pH and ionic strengths, both the sorbent and the ligand linkage must be stable under these conditions.

Highly hydrophilic polysaccharide supports such as agarose, dextran, cellulose, and less frequently starch are often used as supports. Materials based on mixtures of agarose and polyacrylamide, or cross-linked poly(tris(hydroxymethyl)acrylamide) are also commercially available. Recently developed bioaffinity supports include porous poly(styrene–divinylbenzene) beads coated with poly(vinyl alcohol) subsequently cross-linked and activated with epichlorohydrine, butanediodiglycidyl ether,\(^{(292)}\) or glutaraldehyde,\(^{(293)}\) These materials are stable in strong bases and compare well with agarose-based materials.\(^{(294)}\)

### 5.4.2 Activated Supports and Ready-to-use Media

Due to the almost limitless variety of affinity ligands, only a limited number of affinity columns with ready attached ligands are commercially available. These ligands are typically specific for families of affinants, such as carbohydrates, antibodies, etc. Media for more specific separations requiring less common ligands are still usually prepared by reacting the desired affinant with an activated support. This support is either purchased activated or given the required binding properties in the laboratory using a suitable reagent, typically chosen among the activation chemistries listed in Table 4. Activated materials are often delivered in bulk form, and can be characterized before use by titration to ascertain that the material has the specified binding capability. This can be done by attaching the ligand and monitoring the decrease in absorbance or another measurable parameter of the ligand in the attachment solution before and after reaction. The type of activation depends on the targeted functional groups on the ligand, its molecular size, the location of the affinity epitope on the ligand, etc. The choice of support matrix, spacer, activation chemistry, and immobilization conditions is a complex process, largely subject to trial and evaluation. A structured experimental approach is therefore advocated.

Immobilization chemistries on silica matrices are different from polysaccharide matrices in that the reactions used for alkyl hydroxyls in polysaccharide carriers cannot be applied directly to the silanol groups. The first activation step is therefore typically a liquid or gas phase\(^{(296)}\) attachment of a reactive silane spacer, such as 3-glycidoxypropyltrimethoxy silane (GLYMO),\(^{(297)}\) 3-aminopropyltrimethoxy silane,\(^{(298)}\) (3-chloropropyl)trimethoxy silane,\(^{(299)}\) or 3-isothiocyanato-propyltriethoxysilane.\(^{(300)}\) The GLYMO activation is one of the most frequently used, because its reactive epoxy groups, introduced in a single-step reaction, can either be used for direct attachment,\(^{(301,302)}\) or as a starting point for further reactions after an acid-catalyzed hydrolytic ring-opening into a diol.\(^{(303,304)}\) Some other activation chemistries for silica are based on 1,1'-carbodimidade azole (CDI),\(^{(1,305,306)}\) N-hydroxysuccinimide ester,\(^{(307)}\) 4,6-diphenylthi eno[3,4-d]-1,3-dioxol-2-one 5,5-dioxide,\(^{(308)}\) oxalic or adipic dihydrazide,\(^{(309)}\) covalent coupling of tresyl chloride-activated dextran to the sulphydryl groups introduced on silica fibers by silylation with γ-mercapto propyltriethoxysilane,\(^{(310)}\) and conversion into primary hydroxyl

<tr>
<td>Cyanogen bromide (CNBr)</td>
<td>−NH&lt;sub&gt;2&lt;/sub&gt; (proteins, peptides)</td>
<td>Prepared by reacting hydroxylic supports with CNBr under alkaline conditions, resulting in unstable cyanate ester and cyclic imidocarbonate. CNBr activation is particularly useful for agarose sorbents and activation is accompanied by slight cross-linking. Reaction with ligands takes place in aqueous solution at close to neutral pH and forms bonds mainly of the isourea type, which are positively charged (pK&lt;sub&gt;a&lt;/sub&gt; ≈ 9.5). This imparts anion exchanger characteristics to the final affinity matrix. Stability of the isourea bond is limited and subject to aminolysis and to hydrolysis at alkaline pH, which makes CDI a better choice.</td>
</tr>
<tr>
<td>1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC)</td>
<td>−NH&lt;sub&gt;2&lt;/sub&gt; (amino acids, peptides)</td>
<td>Used for activating carboxyl groups to an O-acylisourea intermediate, facilitating formation of amide bonds with amines and thiocesters with sulphydryls. The intermediate is highly sensitive to hydrolysis and must be used immediately upon formation. The reaction has a wide scope in enabling activation of matrix carboxyls that form links to N and S nucleophiles on the ligands, or by activating the ligand and coupling to an amine support. EDC is also widely used for the cross-linking of biomolecules. No spacer is introduced by the EDC chemistry.</td>
</tr>
<tr>
<td>CDI</td>
<td>−NH&lt;sub&gt;2&lt;/sub&gt; (amino acids, peptides)</td>
<td>Capable of activating carboxyls and hydroxyls on supports into reactive carbonylimidazoles and imidazole carbamates, both reacting with amines. Carboxylimidazole-activated supports yield amides with N-terminal and Lys α-amines in proteins, whereas the imidazole carboxylate reacts with nitrogen nucleophiles giving N-alkyl carbamate linkages. Neither link introduces charge to the matrix and coupling to an amine support. CDI provides more stable activated groups than DSC on hydroxyl supports. The activation reagent CDI is extremely sensitive to water.</td>
</tr>
<tr>
<td>N,N'-Disuccinimidyl carbonate (DSC)</td>
<td>−NH&lt;sub&gt;2&lt;/sub&gt; (proteins, low M&lt;sub&gt;W&lt;/sub&gt; substances)</td>
<td>A hydroxyl-containing matrix reacted with DSC yields a hydroxysuccinimide carbonate, which reacts with amines under formation of carbamates. The ligand immobilization reaction can be carried out in neutral aqueous solution or organic solvents. The resulting link is considerably more stable than that formed by the CNBr activation and does introduce a charge to the matrix. Yields less cross-links than CDI.</td>
</tr>
<tr>
<td>Oxirane (epoxy) groups</td>
<td>−SH and −NH&lt;sub&gt;2&lt;/sub&gt; (peptides, proteins)</td>
<td>Oxirane groups are introduced on hydroxylic supports by reaction with epichlorohydrin or diepoxides, which also causes cross-linking. Immobilization of carbohydrates requires alkaline conditions, which calls for a support capable of withstanding high pH. The use of a diepoxide results in concomitant introduction of a spacer arm. Coupling reactions require alkaline conditions (pH &gt; 9 for amines and as much as 11–12 for hydroxyls). The reactivity against thiols is better and can be carried out at neutral pH. Elimination of residual epoxy functionality also requires relatively high pH.Mercaptoethanol can be used, but requires that the ligand lacks easily reduced R−S−S−R bonds.</td>
</tr>
<tr>
<td>Divinyl sulfone</td>
<td>−SH and −NH&lt;sub&gt;2&lt;/sub&gt; (peptides, proteins)</td>
<td>Application area similar to oxirane-activated materials, although the reactivity is higher and permits ligand coupling at pH 1–2 units lower. The final matrices are less stable to high pH conditions than with oxirane-activated materials.</td>
</tr>
<tr>
<td>Reactive sulfonic esters</td>
<td>−NH&lt;sub&gt;2&lt;/sub&gt; and −SH (proteins, low M&lt;sub&gt;W&lt;/sub&gt; substances)</td>
<td>Formed by reacting support hydroxyls with p-toluene sulfonyl (tosyl) chloride or 2,2,2-trifluoroethyl (trelly) chloride, a reaction that is carried out in organic solvent, preferably acetone. This precludes gel matrices that do not swell in solvents. The ligand is attached directly to the carbon bearing the hydroxyl so the coupling chemistry provides no spacer. The stability of the activated support is limited, but storage in weak acid is possible for a limited time prior to ligand coupling. The coupling reaction can be accomplished in water or in organic solvents such as DMF. Tresyl-activated matrices are more reactive than tosyl, and ligand bonding can take place at refrigeration temperature in neutral pH.</td>
</tr>
</tbody>
</table>

(continued overleaf)
groups\(^{311,312}\) for coupling of proteins via hydroxyl-targeting activation reagents. Another viable route is the attachment of a polysaccharide layer\(^{146}\) followed by one of the activation chemistries listed in Table 4.

The conditions during immobilization should be closely controlled and optimized for each immobilized ligand. Obviously, pH is among the more important variables, as the groups targeted on the biological macromolecules are polar groups that are conditionally nucleophilic, dependent on their charge state. For instance, thiolate ions and amines are far more susceptible to nucleophilic attack than thiols and ammonium ions. Type and concentration of buffer, other salts or nonionic agents added to the immobilization solution are also factors that should be controlled. High salt concentrations contribute to decreasing charge repulsion and can be useful in schemes aiming at oriented immobilization.\(^{314}\) As bioaffinity heads towards designed interactions based on peptides and other bio-oligomers, there is a growing need to study the effect of the immobilization chemistry on the reaction micro-environment in the carrier–ligand–solute interaction region. Some of the important parameters are spacer length, ligand loading, mono- and multipoint ligand attachment, and targeted group in the biomimetic ligand.\(^{314}\)

### 5.4.2.1 Spacer Arms

Unexpectedly low binding strength and capacity can be due to steric hindrance if the ligands are immobilized directly onto the sorbent surface. These effects are more often seen for low-molecular-weight ligands and macromolecular affinants having the interaction sites located inside their coil, which is often the case with active sites of enzymes. The problem can be partly alleviated by the use of a spacer arm that extends the ligand from the carrier surface to improve its reach into the binding site of the target solute. The molecules used as spacers are bifunctional chains of varying length, with one functional group capable of attaching to the carrier and the other suitable for immobilization of the ligand. Some molecules that serve as spacers are shown in Table 5.

The use of an alkylene chain spacer introduces a hydrophobic moiety that may increase the undesired nonspecific interactions. The decision to use a spacer should therefore be made only if direct immobilization fails. In general, the shortest spacer that provides good results should be selected to avoid crowding the pore space. The spacer density is also important, as a very high coverage serves only to extend the level of the surface, without providing a real spacer effect. Extension of spacers is possible using reactions related to those used in solid-phase peptide synthesis. For example, supports activated with 6-aminocaproic acid can be extended by another 6-aminocaproic acid segment. Alternating use of a diaminoalkane and succinimide will produce a polyamide spacer that is less polar than the alkylene spacer of the same length. The polyamide with the shortest intra-amide distance is poly(glycine), but the use of a polypeptide as spacer can also lead to nonspecific interactions. It should be noted that many of the immobilization chemistries shown in Table 4, such as oxirane and glutaraldehyde, actually immobilize the ligand at a certain distance from the support surface without the use of a dedicated spacer molecule.

### 5.4.2.2 Capping of Residual Activity

Residual activated groups remaining after the ligand has been immobilized can react with eluent and sample components and must therefore be quenched or capped. This is particularly important with large ligands imposing steric hindrance in the immobilization process, and for activation chemistries
Table 5 Examples of spacer arms used to extend the distance from the support surface to the immobilized ligand

</table>

Warning: Spacer molecules are difunctional compounds designed to react with moieties present in biological molecules and should as such be regarded as toxic by default. Laboratory protocols for attachment of these and other ligands to various activated matrices can be found in the literature.

that are stable in aqueous media. Fortunately, most activation chemistries are sensitive to hydrolysis and the simplest way of deactivating these supports can be to leave them suspended in the coupling buffer for a few days after the ligand has been immobilized. This approach does not work for supports activated with amino and carboxylic groups, which introduce an ion exchanger character to the matrices. It should be kept in mind that capping agents targeting particular functional groups may also attack similar groups on the immobilized ligand, with a risk of altering its properties.

The capping agent is usually a small hydrophilic molecule containing a polar functional group. Examples of these compounds are glycine, TRIS, or ethanolamine, which react through their amine groups. The latter is also useful for quenching of carboxylate functionalities. Amine functionalities can be capped with acetic anhydride, whereas mercaptoethanol, mercaptobenzyl, or cysteine react readily with sulfhydryl groups. In general, quenching agents with terminal hydroxyls provide the most efficient blocking, and capping agents with dual functionalities such as glycine, cysteine, or mercaptoethylamine should only be used when the new functionality introduced is desired.

5.4.2.3 Oriented Immobilization The immobilization of high-molecular-weight ligands such as protein, which possess more than one attachment site, can occur in several different ways and through a variety of functionalities distributed along the chain. Immobilization through a
functional group of, or in close vicinity to, the active site may block the access of compounds and decrease the possibilities of interacting with solutes. These problems were first identified in the immobilization of antibodies, and as a result several techniques have been developed for oriented immobilization. Among them are attachment of antibodies via immobilized Protein A and Protein G, proteins on immobilized antibodies, glycoproteins using their carbohydrate moieties, the use of site-directed mutagenesis, and attachment by means of boronate affinity, metal complexes, and biotin–avidin or streptavidin conjugates.\(^{(315)}\)

5.4.3 Specific Ligands and Practical Considerations

The boronate group of 3-phenylboronic and other immobilized boronic acids\(^{(316,317)}\) is a group-selective small ligand of wide scope through its reversible formation of cyclic boronate esters with coplanar adjacent cis hydroxyls (cis-diols). This forms the basis for efficient separation of low-molecular-weight compounds such as nucleotides, nucleosides, catecholamines, and carbohydrates,\(^{(318)}\) as well as biomacromolecules. Competitive elution is conveniently carried out by adding a low-molecular-weight carbohydrate to the elution buffer. Due to its relatively broad range of target molecules, boronate affinity is often used as a sample preparation and enrichment step for other separative modes. Series coupling with RPHPLC is facile, because the elution conditions in boronate affinity chromatography are rarely effective for eluting the purified substances on an RP column. Bands are thereby sharpened even though relatively large eluate injections are made. The boronate ligand can also serve as an immobilizing group for diol ligands when preparing other affinity chromatography packings. Enzyme substrates can for instance be attached successfully to matrices through this chemistry.

Examples of the use of boronate chromatography are the separation of glycoproteins\(^{(319)}\) (e.g. amylases,\(^{(320)}\) hemoglobin,\(^{(321)}\) and glycosylated albumin\(^{(322)}\)) by elution with sorbitol\(^{(321,322)}\) or step gradients of increasing acidity,\(^{(323)}\) and RNA.\(^{(324)}\) The specificity for diols can also be used for selective enrichment of smaller biomolecules and xenobiotics, such as diadenosine polyphosphates in human platelets,\(^{(325)}\) ribonucleosides in urine and serum,\(^{(326)}\) norepinephrine, epinephrine and dopamine in urine,\(^{(327)}\) and the antiviral drug 1-\(\beta\)-D-ribofuranosyl-1,2,4-triazole-3-carboxamide (Ribavirin) in serum, plasma and cerebrospinal fluid.\(^{(328)}\) There are numerous other examples in the literature of pre-concentration of nucleosides and related compounds on boronate phases. Relatively uncomplicated preparation procedures are also published, based on reaction of 3-aminoboronic acid with epoxidated\(^{(329)}\) or 3-chloropropylated\(^{(330)}\) silica.

5.4.3.1 Biomimetic Interactions

The interaction of the glycopeptide antibiotic teicoplanin with a D-Ala-D-Ala-6-aminohexanoyl ligand on agarose\(^{(331)}\) is a representative of a biomimetic interaction with a small immobilized molecule, imitating a bacterial cell wall component.\(^{(332)}\) An interesting observation made by Berthod et al. is that, when used as a chiral separation ligand for amino acids and dipeptides, teicoplanin has a higher preference for L-Ala-D-Ala than for D-Ala-D-Ala.\(^{(333)}\) Along the same lines, Pingali et al.\(^{(334)}\) attached peptide ligands by direct synthesis onto an amine-functionalized perfusion-type material. The peptide ligands synthesized were GPRP, an effective small synthetic affinity ligand for fibrinogen,\(^{(335)}\) and CAQHTVEK, a cytochrome \(c\) peptide segment to a heme group was covalently attached by linkage to the cysteine thiols in order to achieve biomimetic binding to albumins.\(^{(336)}\) Both resins worked as expected and could be eluted by lowering the pH or by increasing the salt concentration. A representative of steroid ligands is a silica column with attached dexamethasone, used by Formstecher et al.\(^{(337)}\) for the purification of specific antidexamethasone immunoglobulins (Igs) from rabbit antisera. An opposite small molecule interaction worth mentioning is the group-specific affinity of immobilized tomatine, a tomato glycoalkaloid comprising a steroidal part with a four-sugar carbohydrate side-chain, with steroids.\(^{(338)}\)

5.4.3.2 Biotin–Avidin

A strong small molecule/biomacromolecule interaction is the biotin–avidin binding\(^{(339)}\) which is often used in immunoassay protocols. The binding is too intimate to be of direct practical use in affinity chromatography, and the biotin–avidin scheme is therefore probably best utilized as a means for oriented immobilization.\(^{(315)}\) The strong binding has also prompted the development of reversible\(^{(340)}\) and photocleavable ligands,\(^{(341)}\) as well as soluble heterobifunctional biotin affinity–metal chelating polymers capable of expressing biotin–avidin binding and reversible attachment to an immobilized metal ion affinity chromatography (IMAC) sorbent\(^{(342)}\) (see below). The strep-tag technique is a way of using this interaction, where the expensive avidin or streptavidin is replaced by a recombinant core streptavidin comprising a nine amino-acid peptide sequence with streptavidin-binding activity.\(^{(343)}\) Fusion proteins are eluted by addition of biotin to the buffer. Evolving developments along the same lines are fusion of peptide sequences specifying biotinylation\(^{(344)}\) and a truncated rat neurotensin receptor.\(^{(345)}\) The avidin–biotin interaction has also been used for immobilizing liposomes to stationary phases (Figure 24) for studies of drug–membrane partitioning.\(^{(346)}\)
5.4.3.3 Enzyme–Substrate/Product/Inhibitor Interactions

Enzyme–substrate/product/inhibitor interactions provide a means for the separation of enzymes according to the affinity principle. It is difficult to draw clear distinctions between these types of mechanisms, as most enzymes are inhibited not only by their products but also by immobilized substrates, cofactors, and by compounds of high structural similarity to any of these ligands. An example of a substrate interaction is the use of glutathione immobilized via an S-octyl spacer on a cross-linked 2-hydroxyethylmethacrylate carrier for affinity separation of glutathione S-transferase isoenzymes.\(^{(347)}\) Elution is effected by adding glutathione modified with S-alkyl groups of different length to the eluent and the eluate from the affinity separation step can be coupled directly via an on-line coupling to an RPHPLC column.\(^{(348)}\) The best results are obtained with very low flow rates and shallow gradients in the elution step from the affinity column, as seen in Figure 25. This is a good illustration of the poor kinetics in affinity chromatography compared to many other modes of chromatography, due to the typical slow dissociation rates of protein–ligand complexes.\(^{(349)}\)

The interaction of anhydrochymotrypsin with tryptophan immobilized via a six-carbon spacer, based on aromatic amino acids being the cleavage points for trypsin enzymes, has been used for separating anhydrochymotrypsin from related active enzymes.\(^{(350)}\) Cholesterol has analogously been used as a ligand for purification of cholesterol-esterifying enzymes.\(^{(351)}\) The utilization of enzyme–substrate interactions in chromatography and other branches of analytical chemistry was recently reviewed by Freitag.\(^{(352)}\)

An example of a cofactor interaction is the nucleotide analog ligand 8-((6-aminohexyl)amino)-2’-phospho-adenosine-5’-diphosphoribose, which produces a high and specific retention for nicotinamide adenine dinucleotide phosphate (NADP)\(^+\)-dependent enzymes when attached to epoxy activated silica.\(^{(353)}\) Detachment of the retained enzymes can take place either by a salt gradient, or by competitive elution with NADH\(^+\). The reverse principle is also possible, namely immobilization of an enzyme for retaining cofactors and xenobiotic mimetics, as exemplified by the immobilization of alcohol dehydrogenase for separation of adenine nucleosides, adenine nucleotides, and triazine dyes.\(^{(304)}\) Considering the nature of these compounds and the separation efficiency obtained, this separation could probably be better solved with other HPLC techniques.

5.4.3.4 Enzyme–Inhibitor Complexes

Examples of enzyme–inhibitor complexes being used in affinity schemes are replete in the literature. These reactions are normally highly specific and the sorbents are therefore dedicated for the target solute and synthesized by the operator on the basis of unfunctionalized or pre-activated sorbents. Interactions could be divided into...
three categories: protein–protein interactions, and interactions between small molecules (natural or synthetic) where the small molecule is either the ligand, or the separated solute. One of the most widely used protein–protein interactions is the trypsin–trypsin inhibitor complex, and conditions have been published for immobilizing bovine pancreatic trypsin inhibitor to silica and HEMA copolymer particles for affinity chromatographic purification of trypsin and related serine proteases. This type of interaction can be used with either the enzyme or its inhibitor as ligand, providing a means for purifying and separating both the serine proteases and their inhibitors. Similar schemes are available for many other enzymes. Immobilized anhydrotrypsin serves as an example both of a modified enzyme as an affinity ligand, and an enzyme–inhibitor interaction. Anhydrotrypsin is prepared from bovine trypsin by transforming a serine residue at the catalytic site into a dehydroalanine residue. This bereaves the transformed enzyme of its catalytic activity, but a strong affinity against trypsin digestion products is maintained, so that peptides with Arg, Lys, or S-amineethyl cysteine residues at the C-terminus are adsorbed under weakly acidic conditions with high selectivity. A related scheme based on immobilized anhydroelastase, purified on the product analog ligand (Arg)₃ on a hexyl spacer, has also been described as a tool for purification and search for other naturally occurring protease inhibitors. An advanced, ternary indirect immunoaffinity enzyme–inhibitor scheme was recently devised for chromatographic studies of the role of proteases from the same leguminous seeds that are the sources of their inhibitors. Salt elution was used to dissociate the enzymes from a multivalent protease complex purified from winged bean seeds, using an anti-(winged bean) chymotrypsin inhibitor immunoglobulin G (IgG) as ligand.

4-Aminobenzamidine and other benzamidines are examples of synthetic enzyme inhibitors that inhibit the activity of the serine proteases and provide a strong retention for a number of these enzymes when immobilized onto silica due to interactions with their active sites. Another example of a group of synthetic inhibitory ligands are peptide boronic acids, which target chymotrypsin-like proteinases and elastolytic enzymes. Columns with Ala-Ala-boroPhe and Ala-Ala-boroVal attached through their N-termini have a preferential retention for bovine α-chymotrypsin and porcine pancreatic elastase, respectively. A series of thymidine derivatives showing competitive inhibition on thymidine kinase have been attached to agarose carriers and evaluated as affinity media in various orientations with a retained ability to bind thymidine kinase. Chaiken discussed the use of antisense peptides in affinity technology and gave an overview of trends towards molecular recognition and tagging techniques in bioseparations. An example of a natural peptide–protein interaction is the Ca²⁺-dependent affinity of calmodulin for melittin, a 26-residue α-helical peptide present in bee venom that was coupled to GLYMO-activated silica by Foster and Jarrett and used for affinity chromatography of calmodulin.

Synthetic anthraquinone dyes can be considered as a group of ligands with a serendipitous biomimicry, based on the resemblance of the core structure of these dyes, borrowed from the textile dye industry, with adenosine nucleotides and adenine enzyme cofactors. A large number of dyes have been evaluated as affinity ligands but only a limited number, in particular Cibacron Blue F3G-A and Procion Red HE-3B, have become widely used for the purification and analytical separation of nucleotide binding of enzymes such as kinases, dehydrogenases, and ATPases, but also nonenzyme plasma proteins in which case the retention should be considered as emanating from less specific mixed-mode interactions. Some examples of synthetic affinity ligands are shown in Figure 26.

Proteins are bound to the dye ligands by specific interactions with the protein active site or through various nonspecific interactions. In general, protein elution from dye ligands can take place by salt gradients, sometimes with altered pH, but enzymes are often eluted more efficiently and at higher purity if a biospecific eluent component such as a substrate or substrate analog is added to the eluent either continuously at a low concentration or in pulses. Cofactors such as nucleotides are the most common biospecific displacers.

Figure 26 Structures of (a) the synthetic inhibitor benzamidine, (b) the synthetic dye Cibacron Blue, and (c) a recently designed affinity ligand for trypsin-like serine proteases. (Reproduced from C. Koch et al., J. Chromatogr. B, 718, 46 (1998) by permission of Elsevier Science B.V.)
and sometimes an oligonucleotide may also be needed to develop a biospecific solution phase interaction. Selectivity to different cofactors has been used as a tool for separating related enzymes and for differentiating between active and inactive forms of enzymes. Some metal ions (Zn$^{2+}$, Co$^{2+}$, Mn$^{2+}$, Ni$^{2+}$, Cu$^{2+}$, Ca$^{2+}$, Mg$^{2+}$, and Al$^{3+}$) are capable of promoting the binding of certain proteins to dye ligands, whereby chelating agents are used for elution. Ethylene glycol and chaotropic ions may also be employed in eluent schemes to effect elution or for removal of strongly bound components from the affinity matrix. Another synthetic dye ligand is the N-methyl acridinium group, which in different incarnations has been used for purification of acetylcholinesterase. Carroll et al. recently presented a convenient way of preparing an acridinium affinity sorbent by attaching 9-amino-1,2,3,4-tetrahydroacridine (tacrine) to an epoxide carrier in a one-step reaction. Dye affinity chromatography is a mature and highly valuable technique in view of the high selectivities that can be obtained with this set of relatively inexpensive ligands. Stationary phases with various standard dyes are available from a number of suppliers, in the form of conventional soft bioseparation gels and as HPLC columns.

Recent developments in dye affinity chromatography have focused on refining the interaction modes and understanding the interaction processes. Chemistries for immobilization of dye ligands via epoxide-activated spacers instead of the conventional coupling to surface hydroxyls were recently investigated by Scoble and Scopes, who showed that the epoxide immobilization route gave materials with considerably higher ligand density. Mattiasson et al. addressed the nonspecific interactions of dye affinity sorbents by shielding the ligands with layers of nonionic, water-soluble polymers such as poly(vinylpyrrolidone) or poly(vinyl alcohol). The same authors also reviewed new developments in dye affinity for bioprocessing, dealing specifically with new dyes and conditions for the protein–ligand attachment and detachment steps. An interesting extension of this work is their use of water-soluble polymers for protein displacement in dye–ligand chromatography. It was demonstrated that porcine muscle lactate dehydrogenase (LDH) could be efficiently displaced from a blue agarose gel by poly(N-vinyl pyrrolidone) and poly(N-vinyl caprolactam).

As the latter polymer is thermoresponsive, it could be precipitated from the eluate and recovered by centrifugation at 45 °C. PEI was found to be an even more efficient displacer, but requires more elaborate regeneration of the dye–ligand column. Boháčová et al. investigated the solution-phase interactions between seven anthraquinone dyes with and without the triazine moiety on the activity of LDH at different pH. The inhibitory action was found to be dependent on configuration similarity and spatial arrangement of acidic and basic groups in NADH and the tested dyes, which in turn was dependent on the dye acid–base properties (Figure 27).

5.4.3.5 Bioaffinity Chromatography

Antibodies or Igs are multimeric polypeptides expressed by cells as recognizable elements for mediating an immunological response to foreign material. The specific affinity of antibodies is usually very high against biomacromolecules of nonhomogeneous composition and antibodies are therefore capable of highly specific sequestering of proteins, polysaccharides, and other structurally heterogeneous macromolecules from biological fluids. This forms the basis for bioaffinity chromatography. An antibody will be produced against a compound only if the four immunogenicity criteria are met, i.e. foreignness, molecular size, chemical composition, and complexity. However, it is possible to induce the formation of antibodies against haptens, small molecules that are antigenic but nonimmunogenic because of their insufficient molecular weight, by conjugating hapten molecules to a large protein carrier and using the conjugate to induce the immunogenic reaction. The specificity of antibodies against small molecules is usually lower, and a considerable cross-reactivity is quite common. This lack of specificity is problematic in nonseparative immunoanalysis schemes, but can be advantageous for obtaining separation of closely related substances in immunoaffinity chromatography.

Antibodies are either polyclonal or monoclonal. Polyclonal antibodies are produced by immunizing a living organism, monitoring its immunoresponse, and harvesting the produced antibodies from serum. Trapping and purification are often done by the aid of mixed-bed ion-exchange, hydroxyapatite, or HIC, or by some of the IgG-specific affinity schemes described later in this section. Characteristic of polyclonal antibodies is a large heterogeneity in binding strength to the antigen, often to different regions (epitopes) of the antigen. This property can make polyclonal antibodies valuable in enrichment schemes, as exemplified by the on-line extraction of the benzodiazepine flunitrazepam and its main metabolites, and isolation of aflatoxins but they are less useful as mediators of analytical separation due to the substantial variation in binding strengths towards single antigens or haptens. Monoclonal antibodies are produced in immortal cell lines (hybridomas) that are subjected to the antigen or a hapten-carrier conjugate and grown. Individual cells are thereafter selected and used to establish a cloned source of identical antibodies that are produced as long as the cell line is kept alive. It should be realized that each hybridoma cell produces different antibodies following the initial immunization, and that...
The antibody used for analytical recognition is usually IgG, which is a class of tetrameric polypeptides with $M_W$ around 150 kDa. Pepsin digestion of intact IgG produces a fragment $\text{F(ab)}_2$ of approximately 100 kDa containing the antigen recognition elements of the antibody. The remainder is the constant (Fc) region which does not carry specific recognition elements. Both intact antibodies and $\text{F(ab)}_2$ fragments can be used as selective elements on immunosorbents. However, because only the Fc fragment is glycosylated, the possibility of oriented attachment through carbohydrate-directed attachment chemistries (Figure 28) is lost if the Fc fragment of the IgG is removed. The most sensitive part of the procedure is the immobilization of the antibody to the carrier, which could be either a preactivated or an in-situ-activated matrix. The carrier surface properties, the immobilization chemistry, and the conditions used during the immobilization will determine the biological activity of the interaction layer, i.e. to what extent the antibodies are capable of interacting with the antigen. Techniques for oriented immobilization should be considered if immunosorbents with acceptable binding capacity and site homogeneity cannot be produced with conventional chemical immobilization. The kinetics involved in immobilization of antibodies to HPLC supports were recently investigated by Oates et al., for the coupling of periodate-treated IgG to dihydrazide-activated silica. Important factors are the coupling site densities on the antibodies and the support, the amount of antibody in relation to the support, and the reaction slurry density, i.e. the degree of dilution by the coupling buffer. It was found that the density of the activated site on the support has a low influence on the binding rate, which is instead determined by the availability of coupling groups on the antibodies. Enhanced binding is often seen for proteins on epoxy carriers in the presence of cosmotropic salts, explained by an association of the protein to the carrier surface according to a HIC mechanism. The high concentration achieved on the surface by salting-out the protein is supposed to drive the immobilization reaction to a faster completion. Although amine-based buffers are generally to be avoided when immobilizing proteins onto supports activated with electrophilic groups, immobilization can still apparently be enhanced by more than molar concentrations of ammonium sulfate (Figure 29).
Protein A and Protein G are bacterial surface receptors from *Staphylococcus aureus* and *Streptococcus* sp., respectively, which are capable of binding to the Fc fragment of IgGs from many species. The specificity of native Fc-binding proteins differs, with an overlap among Ig classes, subclasses and species where the IgGs are raised. By the use of recombinant techniques, it has become possible to produce A/G fusion proteins which combine the binding capabilities of Protein A and Protein G. All three proteins are commercially available. The important feature is the capability of binding to the Fc part of an IgG, which means that these bacterial receptors can be used for oriented immobilization of intact IgGs and ensuring that the recognitive element is protruding from the surface of the immunosorbent. It is also useful in cases where the IgG has to be replaced frequently on the immunosorbent. Another technique that can accomplish oriented immobilization of IgG is anti-IgG antibodies. The drawback of both these techniques is the relatively high cost of the attachment chemistries.

Examples of affinity separations based on antibodies are numerous in the literature and often tangential to immunochemical analysis techniques, where the ultimate purpose of using the biospecific interaction is not to produce a chromatogram but to isolate and facilitate the detection of a biomacromolecule or a hapten at very low concentrations. A few illustrations of chromatographic uses of immobilized antibodies are in the enrichment of mycotoxins (aflatoxins, ochratoxin, fumonisins, and lysergic acid diethylamide (LSD)). A different kind of specificity was utilized by Kasper et al., who immobilized human IgG to a macroporous glycidyl methacrylate-co-ethylene dimethacrylate polymer disk and used the binding ability of IgG to isolate *E. coli* recombinant Protein G. Histidine was introduced some years ago as a pseudoaffinity ligand. The initial target was IgG, which can be retained and eluted under mild conditions from particulate sorbents or poly(ethylene vinyl alcohol) hollow fibres. Histidine ligands have subsequently proved to be useful for enrichment and purification of many other proteins. Subtractive affinity chromatography on immobilized anti-human albumin and anti-human transferrin IgGs was described by Wheatley as an alternative way of purifying IgG from other plasma proteins. Some HPLC
techniques have also been used to monitor the production of antibodies in hybridoma cultures, by using nonporous silica columns with immobilized Fc receptors.\(^{(404)}\)

5.4.3.6 Chromatographic Studies of Protein–Drug Interactions Studies of the binding of small drugs to immobilized proteins is also a field of biomacromolecule separation that falls within the scope of this article. In reality, this is an inverse affinity chromatography scheme, where the small ligand molecule is presented in the liquid phase to a sequestered biomacromolecule acting as the stationary phase. Knowledge that protein components of blood serum bind drugs differently\(^{(405)}\) necessitates studies of drug–protein binding\(^{(406)}\) in pharmacology. Affinity chromatography on immobilized proteins has been established as a fast and reliable way of conducting these studies, focused on a narrow range of proteins known as carriers of small molecules in blood. A number of recent papers can serve as entry points into this literature. Kalisz\(\text{a}^{(286)}\) reviewed how chemometrics in combination with affinity chromatographic retention studies of drug analytes on biomacromolecular ligands can be used to establish quantitative structure–retention relationships relevant to molecular pharmacology and rational drug design. Layers of keratin\(^{(407)}\) and collagen\(^{(408)}\) covalently bound to silica serve as models for percutaneous penetration. Silica-immobilized melanin is used to elucidate the pharmacologically and toxicologically important binding of many drugs and toxic substances to this localized molecule.\(^{(409} – 411)\) Hage et al. have published a number of studies on interactions between native and modified human serum albumin (HSA), and in a recent work they characterize the specificity and cross-reactivity of a set of drugs that have evolved as indicators for minor binding sites in HSA.\(^{(412)}\) Another major transporter in serum is \(\alpha_1\)-acid glycoprotein (orosomucoid), which binds basic substances preferentially and has been immobilized on agarose and used for selective but nonspecific clean-up of \(\beta\)-agonists from urine.\(^{(413)}\) These techniques should be regarded as a set of tools that can be used in combination with immobilized biomimetic components such as liposomes, proteoliposomes and biomembrane vesicles,\(^{(414)}\) and immobilized artificial membrane chromatography.\(^{(415},416)\) The latter technique is based on partitioning to a phospholipid bilayer similar to a biological membrane (Figure 30), deposited on silica, and has become a valuable tool for screening drug–membrane interactions,\(^{(417)}\) and for determining hydrophobic peptide–membrane interactions.\(^{(418)}\)

5.4.3.7 Designed Synthetic Biomimetic Ligands A trend in specific bioaffinity chromatography is towards designed synthetic biomimetic ligands, which is in line with concurrent drug–protein interaction research. An important additional driving force for this development is the need for highly selective, sturdy, and inexpensive separation techniques for down-stream processing in the biotechnologies.\(^{(419)}\) The anthraquinone dyes described above are intriguing candidate substrates for ligand modification, in order to establish new interactions that are tailored to particular solutes. Consequently, a substantial amount of work has been devoted to the systematic modification of anthraquinone dyes, aiming at developing ligands with more well-defined biomimetic properties.\(^{(420} – 422)\) A more ab initio approach was taken in a recently published work by Li et al.,\(^{(422)}\) where a series of low-molecular-weight ligands mimicking the binding ability of Protein A to IgG were synthesized, based on

![Figure 30](image-url)
X-ray crystallographic studies of the specific recognition and complexation region between Protein A and the Fc fragment of IgG. Immobilized to an agarose carrier, one of these synthetic ligands, “artificial Protein A”, has the ability to bind several IgGs, and can be used to purify IgG from human plasma.

A related approach is to determine amino acid sequences of antibodies, to synthesize these sequences, and to immobilize these synthetic antibodies as biospecific recognition elements. An example of such work is by Lasonder et al., who also used a surface plasmon resonance biosensor to study the interactions. In the area of metal interaction affinity chromatography, Hutchens and Yip used repeating units of the (GHHPH) amino acid sequence to produce a sorbent with similar binding capacity for Cu$^{2+}$ and Zn$^{2+}$ that was used for selective adsorption and isolation of proteins from human plasma.

Based on these results, they suggested that designed metal chelating ligands could be used to elucidate biologically relevant metal-ion-dependent interactions and transfer events in vitro.

5.4.3.8 Lectins A ligand group complementing boronate media for affinity separation of oligosaccharides are lectins, a family of carbohydrate-binding proteins extracted from plants, seeds, and fungi. Lectins derived from different plants target different sugar sequences and result in different selectivities for carbohydrates. For instance, concanavalin A (Con A) binds selectively to internal and nonreducing α-mannosyl residues, whereas wheat germ agglutinin binds to terminal N-glucosamine groups. Jacalin, extracted from seeds of the jack fruit (Artocarpus integrifolia), has a galactose-specific interaction, providing an affinity for proteins with O-linked oligosaccharides. A useful immunochemical feature is its ability to isolate IgA, which has been used to deduce the structure of the IgA core oligosaccharide by enzymatic scission and MS. A wide spectrum of additional lectins have been purified from various sources, showing a substantial differences in their oligosaccharide binding patterns. Release of oligosaccharides from a lectin column is usually accomplished by displacement with asialic or sialic mono- or oligosaccharides or their derivatives, singly or sequentially, depending on the interaction pattern of the lectin ligand.

Lectins have been used in HPLAC since the technique was in its infancy, and many applications deal with the enrichment and separation of small carbohydrate compounds such as nucleotides and substituted monosaccharides. However, the real potential of lectins is a result of the discovery and characterization of lectins with different oligosaccharide interaction patterns from many different biological sources. Lectin interactions have thereby developed into powerful and indispensable tools in modern glycobiology, a branch of science devoted to elucidating the role of carbohydrates in cellular function and recognition. Immobilized lectins are thus used for separation of glycolipids, glycoproteins, and recombinant products based on their glycosylation patterns, and for fractionation of glycopeptides and oligosaccharides derived from glycoproteins. The combination of several lectins in multidimensional separation systems has lately become customary for elucidating complex carbohydrate structures bound to proteins, for instance when used in a multidimensional LC/MS separation system to reduce the complexity of an endoproteinase LysC digest of a recombinant glycoprotein (Figure 31). The preparation of lectin columns and the selectivity of different immobilized lectins in affinity chromatography was recently reviewed by Endo. An extensive listing of lectins and a review of their use in affinity chromatography has also been published in an on-line journal.

5.4.3.9 Sugars and Sugar Derivatives A good illustration that affinity chemistries can be inverted is that lectins are purified on affinity columns with mono- or oligosaccharide ligands resembling their target. For instance, immobilized glucosamine has been employed as a ligand for the micropreparative HPLAC purification of Con A and a glycoprotein can serve the role as the oligosaccharide ligand for separating lectins. Honda et al. attached glucose, maltamine, and lactamine to epoxy-activated methacrylate resins and evaluated these as affinity supports for lectins. Con A, lentil lectins, and pea lectins were quenched by the maltamine resin, whereas ricinus agglutinin, peanut agglutinin, and soy bean agglutinin had a strong specific affinity for the lactamine resin. Using aqueous acetonitrile eluents, they could also use immobilized sugars to group separate pentoses and 6-deoxyhexoses from hexoses. In later works, they used reductively aminated oligosaccharides prepared by hydrazinolysis of ovalbumin and homologous oligosaccharide series as ligands for similar separation purposes.

Lakhiari et al. have presented a series of papers where N-acetylneuramic acid (NANA; sialic acid) is immobilized onto porous silica that has been deactivated by coating with a DEAE-modified dextran layer and activated with several different activation chemistries capable of immobilizing carbohydrates. The rationale for synthesizing these sorbents was the presence of sialic acids in cellular insulin receptor structure, and the materials did indeed express a quasi biospecific interaction with insulin which made it possible to adsorb and separate insulins specifically. The interaction pattern of these materials...
Figure 31 (a) Diagram of the multidimensional LC/MS system used for obtaining the glycopeptide maps shown in Figure 31(b). In the loop positions of three automatically acutated six-port injection valves (A–C) are situated precolumns (10 × 2.1 mm i.d.) with: A, immobilized concanavalin A (Con A); B, an immobilized mixture of four lectins (*Datura stramonium* agglutinin, jacalin, peanut lectin, and amarathin); and C, a 5-µm silica-based C18 stationary phase. The precolumns are connected in series while loaded, then rinsed and desorbed individually onto the analytical column (250 × 2 mm i.d. C18; 3 µm; 120 Å). A diode-array detector (DAD) was used to monitor the separation and an electrospray ionization (ESI) LC/MS instrument was used for final detection after propionic acid/isopropanol (TFA-fix) had been added post-column. (b) Electrospray LC/MS maps of glycopeptides from endoproteinase LysC digest of DSPAz1, a recombinant DNA-derived glycoprotein. The peptide maps are the following: (A) entire digest without affinity prefractionation; (B) nonglycosylated peptides retained on the C18 precolumn; (C) N-linked glycopeptides retained on the Con A precolumn; (D) O-linked glycopeptides retained on a mixed lectin precolumn. The changes inside the boxed region show different patterns with each precolumn. (Reproduced from A. Apffel et al., *J. Chromatogr. A*, 750, 40 (1996) by permission of Elsevier Science B.V.)
is dependent on the immobilization chemistry, a feature predicted to be useful for studying interactions between coated silica grafted with NANA and insulin. Caron et al. studied the binding of biotinylated human brain lectin A to a ganglioside immobilized on a silica coated with DEAE-dextran with the aid of a streptavidin horseradish peroxidase conjugate detection scheme.

A charged carbohydrate ligand with a broad scope is heparin, a 5–30 kDa mucopolysaccharide composed of repeating α-L-dimannuronic acid 2-sulfate and 2-deoxy-2-sulfamino-α-D-glucopyranose-6-sulfate dimers. It has been used for the separation of lipases, phospholipases and kinases, growth factors, steroid receptors, DNA-binding proteins, restriction endonucleases and RNA polymerases, serum coagulation proteins, lipoproteins (LPs), heparin-binding proteins of smooth muscle cell membranes, and selenium-containing proteins. Immobilized heparin has two principal interaction modes – either as a biospecific affinity ligand, as in interaction with coagulation factors, or as a high-capacity cation exchanger, due to its sulfate groups. Elution with salt gradients is prevailing for both interaction modes. Björklund and Hearn prepared high-performance heparin affinity columns by reductive amination coupling of heparin to amino-functionalized silica and discussed the pore filling problem associated with a head-on attachment of these relatively long polyelectrolytes. Ishimura et al. have shown that the heparin-type specificity is not unique to heparin; a similar interaction pattern with heparin-binding proteins could be obtained on polymeric epoxy precolumns onto which they had attached a β-cyclodextrin sulfate, a known synthetic heparin substitute (Figure 32). They also found that elution was easier from this material, and that the hydrolytic stability was better than for the heparin ligand. Heparin-like selectivity for human basic fibroblast growth factor was also seen by Anspach et al. on a sulfonic acid tentacle-type cation exchanger, which had the advantage of being stable under cleaning-in-place conditions.

Nonsulfated cycloexdextrins have also been used as affinity ligands, for the purification of glycogen-bound protein phosphatase G, fungal and recombinantly produced α-amylases, β-amylase and cyclomaltodextrin glucanotransferase fusion proteins. Elution is usually accomplished with buffers containing β-cyclodextrin.

5.4.3.10 Oligonucleotides and Related Compounds

Oligonucleotides and related compounds have been used for decades as affinity ligands for the isolation of DNA-binding proteins involved in transcription, replication, and recombination. The DNA initially used as ligands was nonspecific and derived from calf thymus. Modern DNA affinity chromatography uses specific deoxyoligonucleotide sequences that are synthesized and multimerized before attachment to agarose gels or core-shell latex supports. Quantitative zonal DNA affinity chromatography has been used to determine the equilibrium constants of proteins binding nonspecifically to DNA. Jarrett et al. have developed high-performance DNA affinity supports based on silica and reviewed their use, whereas Wheatley et al. have used epoxide-activated HEMA resins and pointed out the advantage of using a high concentration of phosphate buffer when immobilizing double stranded DNA via a 5′-mercaptohexyl spacer. A dihydrazide activation chemistry that could be used to immobilize RNA was developed by Ruhn et al. Yashima et al. prepared a series of nucleic acid mimetic stationary phases by graft polymerizing the vinyl monomers poly(9-vinyladenine), poly(9-adenylethyl methacrylate), and poly(thymylethyl methacrylate) onto porous silica that had been activated with 3-trimethoxysilylpropyl methacrylate. The resulting columns were used for separating nucleosides and nucleotide dimers and oligomers according to an HIC-like mechanism (Figure 33).

Another nonantibody biomacromolecular interaction implemented on solid carriers is the separation of mixtures of RNA and DNA on immobilized histones, basic proteins that bind strongly to DNA. By using a rather concentrated salt gradient, oligonucleotides can be fractionated into partly degraded and intact RNA emerging as two separate peaks at different eluent salt
concentrations, followed by a single DNA peak at even higher eluent strength.

5.4.3.11 Screening of Combinatorial Libraries Although a large number of natural ligands have already been developed and evaluated, the quest for new ligands continues as the number of new targets grows rapidly. Libraries of both small molecules and mid-sized peptides have been prepared and screened for activity towards different biomolecules. This approach was primarily used in order to discover new drugs. However, these findings have also afforded new affinants for the preparation of powerful separation media for affinity chromatography of biopolymers. Immunochromatographic screening
is based on immobilization of a receptor molecule that is then challenged with a combinatorial library of candidate compounds. The most retained compound is selected for further evaluation. This comprises their preparation in larger scale and immobilization on a support to afford a separation medium for affinity chromatography of the original receptor. Techniques such as introduction of receptors into in vitro biomembrane mimetic structures like liposomes have also started to emerge.  

### 5.4.3.12 Aptamers

Combinatorial technologies developed during the 1990s have made it possible to isolate oligonucleotide sequences known as “aptamers”, which can enter highly specific affinity interactions with a host of target molecules in an antibody-like fashion. These oligonucleotides are produced from random libraries by systematic evolution of ligands by exponential enrichment (SELEX), based on repeated use of affinity chromatography with the immobilized target as ligand followed by enzymatic amplification. Because the PCR technique is used for preparing synthetic biospecific affinity ligands at will. The first application of an aptamer as a ligand in affinity chromatography was published by Romig et al. In a DNA aptamer selected for its affinity to human L-selectin, they achieved good purification and recovery of a recombinant human L-selectin–Ig fusion protein from Chinese hamster ovary cell-conditioned medium. Aptamers have recently also proven their utility in biosensors, and in the future we should expect to see more applications of the aptamer technology in affinity chromatography.

### 5.4.3.13 Immobilized Metal Ion Affinity Chromatography

IMAC is a versatile separation technique for proteins and peptides based on their interaction with certain metal ions sequestered on chelating agents attached to sorbents, and is known under several other prefixes such as metal chelate, metal-ion interaction, and ligand-exchange chromatography. It occupies a position between biospecific affinity and more general techniques of low specificity such as ion exchange. The interaction principle of IMAC is somewhat similar to hydroxyapatite chromatography both in scope and applications. Both techniques are based on metal-ion affinity and are useful for separating and purifying structurally similar proteins. Whereas hydroxyapatite is limited to a defined crystalline medium, with few possibilities of altering the interaction pattern, IMAC offers far more degrees of freedom by the choice of support type, chelating group, metal ligand, loading buffers, and eluent conditions. For detailed mechanistic aspects of protein separation by IMAC, the reader is referred to the literature and to the references dealing with new ligands and eluents below. The applications are numerous and disparate, and IMAC has been reviewed repeatedly. Practical guides are also available in the literature. This article will therefore concentrate on recent developments in separation media and studies aimed to gain a better understanding of the separation mechanisms.

The chelating groups present on the IMAC stationary phase are designed to bind metal ions known to interact with amino acid side chain functional groups that are exposed on the surface of proteins. Soft-to-borderline metal ions such as Cu$^{2+}$, Ni$^{2+}$, and Zn$^{2+}$ (listed in their general order of decreasing interaction strength with proteins) mainly target histidine, cysteine, and tryptophan, but to some extent also surface-accessible aspartic and glutamic acid residues. The binding of a protein is not related to a particular affinity for metal ions, but is dependent on the number and spatial arrangement of these amino acid residues on the protein surface. The use of spacer arms is therefore not as critical in IMAC as in modes where the ligand should reach into the reaction centrum of a protein. Numerous metal-ion chelating groups have been attached to sorbents for use in IMAC, and a critical factor is that the metal ion should be presented in such a way that it is accessible to the protein solutes. The classical chelating group that was introduced by Porath is iminodiacetate (IDA). A chelating group with different properties, also introduced by Porath’s group, is tris(carboxymethyl)ethylenediamine (TED). Both moieties are illustrated in Figure 34.

A difference between these two groups is the number of coordination sites occupied by the chelating agent. Whereas IDA is a tridentate chelator, TED is pentacoordinate. This means that fewer coordination sites are available for interaction with the protein when TED is used as chelating group. A consequence is that metal

![Figure 34](https://example.com/figure34.png)

**Figure 34** Two frequently used chelating groups for IMAC sorbents with metal ligands attached: (a) IDA and (b) TED. Both groups have been immobilized through bonding to a support activated by an epoxy group. Note the difference in available coordination sites on the metal ion.
ions sequestered with TED normally have a lower retention. This difference also reflects the kind of metal ions attached to the different chelating groups. Whereas IDA is typically used with divalent transition metal ions of lower coordination number, TED was originally developed for use with the group III ions Al$^{3+}$, Ga$^{3+}$, In$^{3+}$, and Ti$^{3+}$.(513) Ramadan and Porath have developed a sorbent based on glycine hydroxamate for use with Fe$^{3+}$ as the metal ion. Hochuli et al.(514) although IDA has remained a popular chelating group for this metal ion. Hochuli et al.(515) introduced nitrotriacetate (NTA) as a quadridentate alternative to IDA, especially suitable for hexacoordinate metal ions such as Cu$^{2+}$ and Ni$^{2+}$, leaving two valencies vacant for biopolymer binding. The transition metal ion-mediated retention seen with dye affinity sorbents by Hughes et al.(516) should strictly also be classified as an IMAC-type interaction.

An IDA-functionalized silica for high-performance IMAC was developed and evaluated by El Rassi and Horváth.(517) Wirth et al.(518) developed a new silylation reagent carrying a precursor of the IDA group, which was used to prepare porous and nonporous silica with IDA chelating groups. By using another silylation agent in competition with the IDA silane for available silanols, the density of IDA groups on the surface could be varied, and the IMAC capacity of the porous sorbent leveled off when the coverage with IDA ligand was about 50% of the maximum obtainable. The importance of ligand density control was also demonstrated by Todd et al., in studies of the retention mechanisms of cytochrome c histidine variants constructed by site-directed mutagenesis on Cu$^{2+}$-loaded IDA ligands.(517) Changes in the number of accessible histidines on the protein surface influence the interaction strength, and when multiple interaction points are involved, the binding constant becomes strongly dependent on the availability of metal sites for interaction. The metal ion–ligand stoichiometry is also important; at sufficient chelating ligand density and with less than half the equivalent of metal ions, these become doubly chelated and inaccessible for interaction with the proteins.(517) Further studies on engineered proteins with imidazole added to the eluent have revealed that even a protein with only one surface histidine had an interaction pattern indicating coordination to multiple Cu$^{2+}$ sites on the IMAC support at neutral pH.(518)

Several new chelating moieties have been developed in later years. One of these is a poly(vinylimidazole) with a complexing ability for Cu$^{2+}$.(519) Metalloprotoporphyrins with different metal centers on silica were found to have strong axial metal–nitrogen interactions with L-histidine, where the metal ion dependence follows the order Fe$^{3+} >$ Ni$^{2+} >$ Cu$^{2+} >$ Zn$^{2+} >$ Cd$^{2+}$.(520) These metalloprotoporphyrins phases are also involved in mixed-mode interaction with contributions from $\pi \cdots \pi$ bonding, evident from retention for phenylalanine residues that are normally indifferent in IMAC. An advantage with the protoporphyrin-based chelating groups is the permanent bonding of the metal ion. A silica furnished with $\beta$-diketonaime groups by reacting 3-aminopropylated silica with 3-bromopentanedione has been loaded with Cu$^{2+}$ and used for separating $\alpha$-lactalbumin from milk whey.(521)

Hearn et al. have developed and evaluated a variety of chelating groups. The first in this series was an O-phosphoserine (OPS)-modified agarose that showed a stronger chelating capability compared to IDA for Fe$^{3+}$ and Al$^{3+}$ and a selectivity different from the conventional chelating agents.(522) Chelating groups based on 1,4,7-triazacyclononane (tacn) to which the borderline metal ions Cu$^{2+}$, Ni$^{2+}$, Zn$^{2+}$, Co$^{2+}$, Mn$^{2+}$, and Cr$^{3+}$ were attached have been found useful for chromatography of several standard protein probes, as well as proteins in partially fractionated human plasma preparations (Figure 35). In connection with these borderline metal ions, the tacn-based sorbents showed a new selectivity toward proteins, compared to previous chelating groups based on IDA, NTA, or OPS.(523) In two recent studies, they make use of 2,6-diaminomethylpyridine(524) and N-(2-pyridylmethyl)aminocetate(525) as chelating moieties in connection with Cu$^{2+}$. The different selectivities offered by all these new ligands refine IMAC as a separation principle, but in spite of their demonstrated

![Figure 35 Elution profile for defibrinylated human serum protein preparation separated on an im-Cu$^{2+}$-tacn-Sepharose CL-6B sorbent using a salt gradient from 20 mM sodium acetate–100 mM NaCl, pH 4.0, to 20 mM sodium acetate–1 M NaCl, pH 4.0, at a flow rate of 0.5 mL/min]. (Reproduced from W. Jiang et al., Anal. Biochem., 255, 53 (1998) by permission of Academic Press.)
utility, commercial availability is a problem with all the less-common chelating sorbents. Therefore, IDA remains the most widely used sorbent functionality and is available from several sources. Development of an IMAC separation method can be simplified by choosing as the initial system a commercially available chelating support with IDA groups and a strongly interacting metal ion such as Cu$^{2+}$. If elution becomes difficult, the less retentive metal ions Ni$^{2+}$ and Zn$^{2+}$ should be tested. If these systems do not work, consider alternative chelating groups and metal ions.

As in other interaction chromatographic modes based on polar functional groups, eluent molecules (solvent or buffer substances) will occupy the metal coordination sites in the absence of proteins interacting with these sites. Protein sorption is therefore connected with a metal ion–ligand exchange. It has to be realized that IMAC sorbents are inherently ionic and thus exhibit a conventional ion-exchange capacity; in particular when the immobilized metal ion is a hard Lewis acid. In order to harvest the specific interaction patterns offered by the lone pair Lewis base–Lewis acid ligand exchange mechanism, eluents should therefore always contain salt, and the salt concentration is not uncritical. An implication is that IMAC can be used to separate proteins eluted from ion-exchange columns without intervening desalting, provided that proper adjustments of pH and salt concentration are made before the sample is loaded onto the IMAC column.

There are several ways to control the retention in IMAC and the easiest and most controllable way of eluting the adsorbed proteins from the column is through gradients of decreasing pH or increasing concentration of imidazole. Samples are normally loaded from neutral or weakly alkaline buffers. The pH gradients operate by changing the degree of ionization of histidine and other interacting groups on the protein surface, whereas the imidazole gradients act by competing for the metal chelating binding sites. Gradient pH elution works with most retained proteins, unless the binding is too strong, in which case a less-retentive chelating group could be considered. Phosphorylated amino acids, phosphopeptides and phosphoproteins interacting with Fe$^{3+}$–IDA are exceptions, where elution is accomplished by increasing the buffer pH or the phosphate concentration, or by using phosphoserine or a displacing metal ion such as Mg$^{2+}$. This specific type of interaction is particularly valuable for trapping low concentrations of phosphoproteins for MS analysis. Displacement of proteins from Cu$^{2+}$ complexes can take place by substituting ammonium for the loading buffer salt cation (which should obviously not be ammonium ion or an amine such as TRIS). Imidazole is also a widely used eluent with Ni$^{2+}$ and Zn$^{2+}$ IDA chelates, where its advantage over pH gradient elution is that the metal ions remain on the sorbent during elution. Elution by decreasing pH and increasing imidazole gradients produce similar elution patterns, as shown by Yip et al., who investigated the interactions of a large number of synthetic peptides (up to 42 amino acids long) on a polymeric high-performance IMAC sorbent with IDA groups and Cu$^{2+}$, Ni$^{2+}$, and Zn$^{2+}$ as metal ions. A third way of eluting is to add a chelating agent such as ethylenediaminetetraacetic acid (EDTA) to the eluent. This procedure will also release the metal ion from the immobilized chelate, in which case the column must be reloaded before next use. However, leakage of metal ions does take place with most eluents, in particular if compounds having a strong interaction with the metal ligands such as glycine or primary amines are present in the eluent, so a prudent practice is to always reload between runs, unless a very stable chelate is used in the column. A reloading cycle typically comprises stripping off remaining metal ions with a complexing agent such as EDTA at neutral pH, followed by reloading of metal ions onto the chelating groups on the sorbent.

The IMAC technique has become part of a unique biotechnological purification scheme through a technology known as “His-tagging”. This tagging takes place by extending the nucleotide sequence coding for a protein to be produced by recombinant technology by the codons for a chelating peptide, generating the gene for a chimeric metal-chelating peptide–protein that can be cloned and expressed. The metal-chelating peptide fusion handle is thereafter used for IMAC purification on an Ni$^{2+}$–NTA resin, whereafter it is removed by chemical or enzymatic cleavage so that the protein regains its natural amino acid sequence. Inclusion of a terminal sequence consisting of six histidines is most common, although fewer histidines in controlled sequences provide for weaker interactions and possibilities of using softer elution conditions. A technique related to His-tagging has recently been used to bestow IMAC retention to DNA produced in a PCR scheme. The His-tag IMAC interaction has also been used for oriented immobilization of antibodies for immunoaffinity chromatography. A recent paper furthermore describes the use of a His-tag in combination with anti-His-tag antibodies for a tandem affinity (IMAC and immunoaffinity) separation of His-tagged proteins. An example of an IMAC separation based on his-tagging is shown in Figure 36.

Metal ion affinity can be used for reversible immobilization of native proteins to affinity-sorbent surfaces, as shown by the preparation of an affinity phase with variable and controlled amounts of Con A using Cu$^{2+}$ chelated to IDA porous silica. Although a wide range of eluent conditions could be used without loss of the
lectin, its detachment could still rapidly be accomplished by eluting with low pH or EDTA. The existence of dual functionalities produced a mixed retention mechanism, characteristic of both IMAC and lectin affinity chromatography.

A different kind of metal interaction chromatography takes place on organomercurial resins, whereupon nucleosomes containing transcriptionally active chromatin unfold and uncover the sulfhydryl groups of a histone, enabling its interaction with reagents having affinity for sulfhydryl groups.

5.4.4 Salt-promoted/Thiophilic Adsorption Chromatography

Porath et al. discovered in 1985 that thioether–sulfone gels, prepared by activation of agarose by divinylsulfone and coupling of 2-mercaptoethanol (Figure 37), have an enhanced affinity towards certain human serum proteins, in particular Igs. The retention appeared to be unique and quite different from hydrophobic interaction, and it works for all three major classes of Igs and their subclasses. This particularly mild technique, which was termed thiophilic adsorption chromatography (TAC), provides for efficient recovery of pure Igs at neutral pH from complex biological matrices. Synthesis of surface-functionalized rigid material for high-performance TAC has also been described. TAC has also been carried out in the membrane format.

The TAC method is a typical on–off affinity technique. The sample is loaded onto the column in a 10–100 mM buffer at neutral pH, to which a 0.5–1 M solution of a cosmotropic salt, typically sodium, potassium, or ammonium sulfate, has been added. The buffer type does not appear to have any significant influence on the result. Examples of buffers are phosphate, borate, and zwitterionic aminosulfonic acids. Although the target is retained, the nonadsorbed molecules are washed away by the running salt-containing buffer. Elution occurs once the mobile phase is changed in a single step to the buffer solution only, or by a gradient of decreasing concentration of the adsorption-promoting salt. Figure 38 shows a separation of mouse Ig subclasses. This facile attachment and detachment of Igs furthermore allows TAC media to be used as immobilization sorbents in flow immunoassays.

Apart from Ig purification, thiophilic adsorption sorbents have also found use as stationary phases for the separation of amylases and for purification of allergens from horse sweat. Experiments by Noel et al. have shown that the presence of a thioether moiety is not essential to promote adsorption of Igs by thiophilic stationary phases. Instead, their ability to retain Igs appears to be connected

![Figure 36](image_url) Anti-His-tag immunoaffinity chromatography of a His-tagged mini-antibody (a homodimerized single-chain Fv fragment with a His8-tag fused to the C-terminus via a linker; sequence scFv-GGSAPGHHHHHHH) after preliminary purification by IMAC. The affinity stationary phase contains an anti-His-tag antibody (3D5) immobilized onto an Affi-Hz hydrazide support. with the divinylsulfone activation/cross-linking, making “thiophilic” a somewhat inappropriate name for what is in reality a salt-promoted retention effected by varying concentrations of kosmotropic anions (compare HIC). This observation was subsequently verified by others.\(^{272,557,558}\)

Several new separation media have recently been synthesized, partly as a result of these findings, by attaching propylamine, allylamine, aminoacetonitrile, 2-aminoacetonitrile, 1,2-diamino-maleonitrile and tri-cyanoaminopropene to 1,4-butanediol diglycidyl ether and divinyl sulfone activated agarose.\(^{559}\) In this study it was found that the nature of the spacer arm and cyano-substitution in the ligand influenced the affinity for proteins, and that the agarose activated by divinyl sulfone and reacted with triacyanoaminopropene had the highest adsorption for proteins. This ligand was consequently studied further and was found to have unique adsorption properties for proteins with binding being both dependent and independent of promotion by salt, which led to a proposed electron donor–acceptor adsorption mechanism for the observed interactions.\(^{560}\) Results by Schwarz et al.\(^{546}\) and Scholz et al.\(^{557,561}\) show that heterocyclic ligands may be a viable route to selective sorption of Igs from solutions of low salt concentration. It thus appears that the salt-promoted “thiophilic” adsorption principle is not limited to antibodies, but is of a more general nature.

### 5.4.5 Multidimensional Affinity Chromatography

The high specificity of affinity chromatography, the relative insensitivity to variations in buffer conditions during the binding step, and the highly specific elution schemes make it possible to combine several affinity chemistries in a single separation. For instance, immobilized anti-HSA and protein A were bound to different chemistries in a single separation. For instance, immunoschemes make it possible to combine several affinity during the binding step, and the highly specific elution relative insensitivity to variations in buffer conditions

#### 5.5 Ion-exchange Chromatography and Related Techniques

Ionic separation materials have been used in biopolymer separations for more than half a century and IEC (or electrostatic interaction chromatography as it should probably be called) has become one of the most widely used techniques for analytical and preparative separation of proteins.\(^{565}\) It is also applicable to other charged biomacromolecules. The popularity comes from an excellent separation power, good possibilities of tuning the separations by selecting columns containing a variety of commercially available stationary phases with many different ionic functional groups, a soft interaction mode due to the buffered fully aqueous salt gradients typically used for elution, and a high sample capacity. The IEC technique is therefore often used in the early preparation stages where overloading is more likely to occur. Ion exchange is also often part of mixed-mode techniques (see below), where an additional separation dimension is allowed to contribute to the overall separation. Books dedicated to IEC are not abundant in the recent literature,\(^{566}\) but chapters on IEC are found in most books on HPLC of biological macromolecules.\(^{565,567–570}\)

The separation principle is based on electrostatic interactions between fixed ionic charges on the stationary phase and oppositely charged functional groups on the surface of the solute molecules. The retention is controlled by the charges of the stationary phase and the solute, and the ionic strength of the medium. Ions that are electrostatically attached to the ion-exchange groups are referred to as counterions, whereas ions of the same charge sign as the ion exchanger are termed co-ions. The fixed charges of the ion-exchange material can be either anionic, in which case the material is a cation exchanger, or cationic, giving the properties of an anion exchanger. Ion-exchange materials are also classified as weak or strong, depending on whether the ionic functional group has a dissociation or protonation equilibrium in the operational pH range, or maintains its charge when pH is changed. A compilation of the most common ion-exchange sorbent functionalities used for biomacromolecule separations is presented in Table 6.

Due to adjacent group effects and changes in solvation and cross-linking, there is a wide span in apparent pK values of individual functional groups in weak ion exchangers, manifested in shallow titration curves, often with steps. The pK values in Table 6 are therefore only approximate. This functional group heterogeneity affects weak anion-exchange materials in particular, where for instance materials based on cross-linked PEI\(^{150}\) contain a mixture of primary, secondary, and tertiary amine groups, whereas DEAE materials contain tandem functionalities where one DEAE group is reacted on top of another
in a quaternizing reaction, leading to a relatively wide distribution in pK. The titration curve of a weak anion exchange resin can thus take the shape shown in Figure 39.

From these curves, it is also apparent that the charge density of a weak anion exchanger is substantially influenced by the ionic strength of the medium, which typically changes during gradient elution. Optimization of separations on weak ion exchangers can therefore be complicated and strong ion exchangers (the S or Q types) are often preferred because they provide a more predictable retention through their lack of disturbing dissociation and protonation equilibria. The retention at varying pH is thereby governed only by changes in charge of the solute. Another parameter affecting the retention is the charge density of the ion-exchange material, which is one of the factors controlling the selectivity.

The versatility stems from the fact that practically all biomacromolecules, with asialic polysaccharides being the notable exception, have functional groups that are charged, or can become charged through dissociation or protonation equilibria within the normal operating pH range of biopolymer separations. This sensitivity to changes in pH provides a key to tuning the selectivity in IEC and also provides for different IEC separation dimensions for the same biomacromolecule. A protein is characterized by its pI, where its net charge is equal to zero. The dissociation of acidic groups and protonation of basic groups on the protein surface produces a negative charge when the pH is increased above the pI value, and conversely results in a positive charge when the pH is lower than pI. A protein can therefore be separated on both anion- and cation-exchange columns, provided its pI is not extreme and the pH stability is sufficient. In principle, a protein should not have retention, neither on an anion exchanger nor on a cation exchanger, at its exact pI as illustrated in Figure 40.

The steepness of the titration curve is quite different among proteins, as is the pI, and even subtle differences, such as the substitution or deamidation of a single-surface amino acid, can cause a sufficient difference in charge properties to allow separation by IEC. The charge properties are mediated by acidic and basic lateral groups in blood coagulation factors, and phosphoserine in phosphoproteins also contribute to the charge of such proteins.

![Figure 39](image-url) Ionization of a pellicular PEI weak anion exchanger as a function of pH and ionic strength. The curves are obtained by titrating with 0.1 M HCl in both distilled water and 1 M NaCl. (Reproduced from W. Kopaciewicz et al., J. Chromatogr., 266, 14 (1983) by permission of Elsevier Science B.V.)

* a The linkages are those often used on polysaccharide materials. Functional groups attached to synthetic polymers may be slightly different.
* b Common abbreviation used by column manufacturers to identify the functional group.
* c pK values of polymer-bound ionic groups are approximate and dependent on the functional group structure, the polymer matrix, steric factors, ionic strength, etc. Titration curves are typically shallow, which means that the net surface charge cannot be calculated directly from the pK.
* d Operational pH range determined by the ionization equilibrium of the ionic/ionogenic group. Other factors may limit this range.
As just mentioned, a noncharged molecule should not interact with an ion exchanger through electrostatic mechanisms. However in practice many proteins do interact significantly with ion-exchange sorbents at their pI, causing a retention that is commonly attributed to an inhomogeneous charge distribution on the molecule surface.\(^{\text{577}}\) A biomacromolecular solute with zero net charge can thus have charge patches of either sign, providing “contact surfaces” with the ion exchange material. For this reason it is often postulated in the literature that proteins have preferred orientations in their interactions with charged surfaces. Because ionic interactions act over relatively long ranges and through gradients that extend from the surface, this heterogeneous charge distribution can enable the molecule to get attached to both anion- and cation-exchange resins at its pI, using different orientations. The steepness of the titration curve appears to be involved in determining the extent of electrostatic interaction at the solute pI.\(^{\text{577}}\)

A central parameter in the discussion of retention in IEC is the \(Z\) number,\(^{\text{571}}\) which is used to visualize the number of charged sites involved in the interaction between the solute and the ionic stationary phase. The \(Z\) number is determined as the steepness of the relationship between \(\log k^0\) and the logarithm of the molality of the eluent obtained from a series of isocratic elution experiments. Because \(Z\) numbers usually assume rather high values, high resolutions can be obtained in IEC as a result of the reasons discussed above for hydrophobic separation techniques.

In its most simplistic form, the force between the charges on the sorbent involved in the interaction \(Z_s\), and the corresponding charges on a biopolymer solute \(Z_p\), separated from each other by the distance \(r\), follows Coulomb’s law (Equation 25),

\[
F = \frac{Z_s Z_p}{D r^2}
\]

where \(D\) is the dielectric constant of the solvent. Ionic interaction forces are therefore weaker in water with

a dielectric constant close to 80, compared to typical water-miscible organic solvents used as eluents, whose
dielectric constants are in the range 20–30. Concerning
the retention mechanism for IEC when operated in fully
aerobic solution, there are two conflicting views. The
traditional retention model, which has its roots in the
1955 Boardman and Partridge’s paper, is based on the
conception that a stoichiometric exchange of counterions
takes place on the sorbent when the protein docks at
the surface. This model, referred to as the KRFR model,
was formalized and verified on experimental data over a
limited concentration range by Kopaciewicz et al. In a large number of subsequent works by many authors,
this empirical model has served as a tool for modeling
the retention within the eluent concentration and sorbent
charge density ranges normally used in IEC, and has
provided data that are meaningful in the context of pI
and charge densities on protein surfaces. The KRFR
model is based on the linear relationship that appears to
exist between log k and log I, where each protein has a
characteristic slope, Z, interpreted as the number of ionic
groups on the protein that are involved in the interaction
process. The Z numbers are therefore dependent on the
charge status of the protein and hence on the pI. The
KRFR model has later been expanded to include the
shorter range van der Waals interactions in order to
account for retention observed on ion-exchange materials
at high salt concentrations due to the hydrophobic effect.

A rather different view on the retention process was
presented by Ståhlberg et al., who applied ideas from
particle interaction in colloidal science to explain the
retention in terms of long-range interactions based on
averaging the charge of the protein and treating the
sorbent surface as a charged flat slab (the SJH model).
In terms of predicting retention, the main difference is
that the SJH model forecasts log k to be a linear function
of the logarithm of the inverse square root of the ionic
strength I, instead of the logarithm of the inverse first
power of I, as predicted by the KRFR model. The first
version of the SJH model could account only for the long-
range electrostatic interactions. Subsequent refinements
have also taken van der Waals interactions and charge
regulation theory into account. The current model
can couple the slope of the titration curves of proteins
at the pI to retention at zero net charge, which can
take place even on sorbents with the same net charge as
the protein (Figure 41). A mechanistic treatment of the
KRFR model (the RUL model) has been introduced, taking into account protein size and net
charge and adopting a simplified form of the sphere–plate
concept, on which the SJH model is based. Similar to the
KRFR model, the RUL model explains log k as being a
linear function of log I. However, according to Ståhlberg’s
recent review of retention models for IEC, the RUL
model is applicable only when the distances between the
protein and the ionic surface are long. The SJH model is
supported by studies of ionic retention on SEC materials
with very low charge density, a situation that cannot
be treated by the KRFR model and its extensions. Yet at
present the tradition model continues to prevail, and as pointed out by Roth et al., the experimental
data that were correlated on a log versus log square root
plot to verify the SJH model can also be fitted to the
KRFR model with a log–log plot.

Figure 41 Gradient elution of β-lactoglobulin (Lg) A and B
(pI ≈ 5.1 and 5.2, respectively) near their pI:s with (a) anion-
exchange chromatography and (b) cation-exchange chromatog-
raphy. The gels (see legend in Figure) were packed in glass
columns (150 x 8 mm i.d.) and eluted with a gradient from 30
to 500 mM NaCl in 10 mM acetate buffer, pH 5.2, at a temper-
ature of 25°C and a flow rate of 1 mL min⁻¹. The gradient rate
was chosen to accomplish baseline separation of LgA and LgB.

Among the more interesting developments in IEC during
the 1990s are tentacle gels and perfusion media. The
latter behave similar to other IEC resins, except that the mass transfer is improved, and are treated in a separation section of this text. Tentacle ion-exchange materials are produced by surface-initiated graft polymerization of linear oligomers combs, comprised of monomers with lateral ionic groups comprising 5–50 charged moieties per ligand unit, amounting to a length of up to $\approx 10\text{ nm}$ in the fully extended state.\textsuperscript{(163)} These tentacle gels were found to absorb proteins to a degree which by far exceeds a monolayer coverage, and exhibit up to four times higher protein sorption capacity compared to corresponding surface functionalized materials.\textsuperscript{(88)} A seemingly rational explanation for this high capacity is that the protein must be adsorbed in multilayers or dissolved within the polymer layer.\textsuperscript{(88)} However, this cannot be contemplated in view of more recent theories of protein interaction with ion-exchange sorbents founded in colloid science, as discussed above. Recent experiments by Ratnayake and Regnier,\textsuperscript{(586)} based on a series of tentacle-grafted cation-exchange sorbents synthesized with varying ligand density and tentacle length, have shown that the retention mechanism of tentacle ion exchangers is similar to surface functionalized materials. It was also concluded that some cross-linking exists in the tentacle layers prepared by free radical grafting, so that not all the polyacrylate chains are in fact tentacles. Another investigation has linked the higher capacity of tentacle gels to the increased flexibility of the ionic functional groups.\textsuperscript{(587)}

Hearn’s group has also conducted several studies on tentacle ion exchangers. When comparing tentacle type and conventional polymeric surface functionalized anion-exchange material,\textsuperscript{(588)} they found that the retention followed a $\log k’$ versus $\log I$ relationship, and that some proteins were not, or only weakly, retained in spite of an eluent pH that was several units above the protein pI. There were also significant differences between a silica-based and a polymer-based tentacle material used in these tests. In a study of salt and pH effects on band broadening,\textsuperscript{(589)} the two types of tentacle materials tested behaved quite differently. These differences were attributed to a dynamic interplay between the tentacle ligands and the protein solutes. On studying the adsorption of different proteins in batch experiments with a silica-based tentacle cation exchanger,\textsuperscript{(590)} it was found that most tested proteins were absorbed according to an ion-exchange mechanism. Lysozyme and insulin were the only exceptions, for which the sorption capacity increased with the concentration of salt. This odd retention behavior was interpreted as a hydrophobic effect. In a comparative study of two grafted strong cation-exchange materials\textsuperscript{(584)} - a tentacle-type material and a polysulfoethyl aspartamide-coated silica - the Z numbers for the tested proteins were found to be higher for the tentacle gel, indicating that the flexible interaction layers interact with proteins through larger contact areas. The hydrophobic contribution to the retention also appeared to be higher on the polysulfoethyl aspartamide material. In a study of the bandwidth characteristics of the same sorbents at different temperatures,\textsuperscript{(591)} band broadening induced by unfolding generally occurred at a higher temperature for the tentacle material. At lower temperatures, the tentacle material appeared to undergo morphological changes, which influenced the bandwidth of eluted proteins.

An advantage of tentacle gels that has been demonstrated in several difficult protein separations is the low hydrophobic interaction, which results from shielding of the underlying support by an extended layer of ionic polymer combs.\textsuperscript{(163)} For instance, Rögnér\textsuperscript{(592)} showed that an early tentacle-type material provided the best separation power for membrane-protein complexes isolated from cyanobacterial thylakoid membranes with detergents above the critical micelle concentration (CMC). Fricke et al.\textsuperscript{(593)} used the low hydrophobicity to purify casein-cleaving membrane proteinase on a strong anion-exchange tentacle material. Purification of these solubilized membrane proteinases could not be done with conventional techniques because the proteins bound irreversibly to all the other stationary phases tested. A high retention ascribed to self-aggregation and strong hydrophobic interactions was also seen with the tentacle materials, but this was solved by an unusual elution scheme with 2-propanol and a decreasing salt gradient. Tentacle materials have superior capabilities of resolving proteins with subtle differences. For example, a cation-exchange tentacle material baseline separated bovine, horse, and rabbit cytochrome c variants, native ribonuclease A and its deamidated Asp67 and isoAsp67 forms, and monoclonal antibody variants differing by a single lysine at the heavy chain C terminus, and hemoglobin variants\textsuperscript{(575)} (Figure 42).

Furthermore, flexible ionic tentacles have a unique biomimetic resolving capability for proteins known to interact in vivo with biopolymers having regularly spaced charges. The heparin-mimicking capability of sulfonated tentacle materials has been demonstrated by Cacia et al.,\textsuperscript{(594)} who separated recombinant human deoxyribonuclease I (rhDNase) variants differing in deamidation of the heparin-like structure for purification of recombinant human basic fibroblast growth factor.

Separation of proteins and peptides is the main application of IEC, but other charged biopolymers such as polynucleotides,\textsuperscript{(595)} glycoprotein oligosaccharides,\textsuperscript{(596)} and neutral carbohydrates can also be resolved by ion exchange, the latter by high pH anion chromatography.\textsuperscript{(567)} Separations of proteins have been made using anion and cation columns in series and with a singular...
column packed with a blend of anion and cation exchangers. However, these dual mode operations do not appear to be widely used.

Binding of biopolymers to the stationary phase takes place from a loading buffer that has its pH adjusted so that the charge of the proteins is opposite to that of the immobilized charged groups of the sorbent (below the pI for cation exchangers, and above the pI for anion exchangers). The salt concentration should also be sufficiently low to avoid elution of the solutes during loading. Sharpening of the injected band takes place at the top of the column and elution does not occur until the mobile phase composition meets the requirement for solute detachment. Conditions used to promote elution are either an increase in salt concentration or, less commonly, a change in pH towards the pI of the adsorbed solutes. A combination of both is also possible. Addition of organic solvents to the eluent can also be used to alter selectivity.

The selectivity can to some extent also be controlled by the type of displacer ions. Kopacievicz and Regnier investigated a number of different salts and classified the displacing capacity of eluent ions from weak to strong. They concluded that the best salts were those where the ions had intermediate eluting capacity, as they were able both to spread out the chromatogram and provide good protein recovery. The same group has also investigated the combined use of salts and solvents to affect retention in HIC and IEC. Hearn et al. studied the effect of different displacing salts on retention and band broadening of proteins in isocratic anion chromatography. The retention order was found to correlate well with decreasing hydrated ionic radii of the eluent anions and the retention was also affected by the type of cation, an effect attributed to preferential interactions with the protein solute. Band broadening was related to Hofmeister effects on the protein and on the double layer interface between the stationary and mobile phases. Malmquist and Lundell employed principal component analysis to find patterns in protein retention data using a large number of salts with cation and anion exchangers at different pH. They concluded that there is a limited possibility of using salts to establish selectivity in IEC, but the most significant effects seen in their experiments were due to changes in the eluent strength of the starting buffer and the alteration of the apparent gradient slopes due to the use of buffer ions of different valence. They also point out that salt effects are more pronounced for late-emerging peaks, which are eluted in a higher salt concentration, and that chaotropic ions are the best candidates for establishing a unique salt-mediated selectivity. Due to the pronounced influence of pH on the charge state of biomacromolecular solutes, proper buffering is obviously very important in IEC. Apart from intended interaction between the ion-exchange surface and the biomacromolecular solutes under study, interactions between solutes and absorbed proteins already present on the surface, for instance due to fouling of the column, should be taken into consideration.

5.5.1 Hydroxyapatite Chromatography

Hydroxyapatite, $\text{Ca}_5(\text{PO}_4)_3\text{OH}$, is a crystalline solid formed by thermal treatment of calcium phosphate in sodium hydroxide solution. The surface affords amphoteric interactions, mediated by the calcium ions and the oxygens attached to the phosphate atoms in the crystal, and the crystal surface offers interaction sites with different properties. Carboxylic groups, basic moieties, and phosphate groups of various biopolymers interact with hydroxyapatite crystals, forming the basis for soft high-capacity multimodal separations. The technique is best characterized as a steric IEC, made possible by the regularly spaced ionic binding sites at the crystalline surface of the sorbent. The separation properties of hydroxyapatite are unique and offer an unparalleled selectivity that can be used to separate proteins that co-elute in other chromatographic modes. As the individual interactions are relatively weak, this method is not well suited for the separation of low-molecular-weight compounds that are only weakly retained. In contrast, the best results were observed for intermediate to large proteins and nucleic acids. The separation mechanism of hydroxyapatite columns, which seems to rely on the formation of complexes between proteins and ions in the mobile phase, was found to control the adsorption of proteins. These processes
can also alter the ionic composition of the hydroxyapatite surface.\textsuperscript{122}

The most important applications are separation of subtly different proteins such as antibodies and their fragments,\textsuperscript{608} isoenzymes\textsuperscript{609} protein toxins,\textsuperscript{608} histone complexes,\textsuperscript{610} phosphoproteins,\textsuperscript{565} LPs,\textsuperscript{611} and solubilized membrane proteins.\textsuperscript{612} Hydroxyapatite chromatography can also be used for the separation of polynucleotides such as t-RNA\textsuperscript{613} and high-molecular-weight RNA.\textsuperscript{614} and glycosaminoglycans.\textsuperscript{615} Protein samples are loaded onto the column at a neutral pH from a low concentration phosphate buffer, and the elution is accomplished by a phosphate buffer with increasing concentration at neutral or slightly alkaline pH. Depending on the kind of groups taking part in the interaction and the number of such groups suitably exposed on the solute, the final buffer strength needed to elute the solutes typically varies from 50 to 500 mM. Low column temperatures should be avoided when the more concentrated phosphate buffers are used to prevent the salt from crystallization. The eluent acts by competing with the proteins for the calcium binding sites. Elution can also be effected by other calcium-binding anions such as citrates.

The most important applications are separation of subtly different proteins such as antibodies and their fragments,\textsuperscript{608} isoenzymes\textsuperscript{609} protein toxins,\textsuperscript{608} histone complexes,\textsuperscript{610} phosphoproteins,\textsuperscript{565} LPs,\textsuperscript{611} and solubilized membrane proteins.\textsuperscript{612} Hydroxyapatite chromatography can also be used for the separation of polynucleotides such as t-RNA\textsuperscript{613} and high-molecular-weight RNA.\textsuperscript{614} and glycosaminoglycans.\textsuperscript{615} Protein samples are loaded onto the column at a neutral pH from a low concentration phosphate buffer, and the elution is accomplished by a phosphate buffer with increasing concentration at neutral or slightly alkaline pH. Depending on the kind of groups taking part in the interaction and the number of such groups suitably exposed on the solute, the final buffer strength needed to elute the solutes typically varies from 50 to 500 mM. Low column temperatures should be avoided when the more concentrated phosphate buffers are used to prevent the salt from crystallization. The eluent acts by competing with the proteins for the calcium binding sites. Elution can also be effected by other calcium-binding anions such as citrates.

The advantageous selectivity of hydroxyapatite has also prompted the investigation of less closely related materials such as lead phosphate hydroxyapatite,\textsuperscript{624} or aluminum and zirconium (hydr)oxide,\textsuperscript{625} onto which phosphate was stoichiometrically bound. All these materials show some features similar to hydroxyapatite, but also large differences. Calcium hydroxyapatite from bones was also evaluated.\textsuperscript{15} A different use of the protein-retentive power of hydroxyapatite is in deproteination steps, as part of the sample preparation procedures in the analysis of small molecules.\textsuperscript{625}
elution proceeds. In general, the starting pH should be above the pI of the proteins to be separated (usually 0.5–1 pH unit higher), although this may not always be necessary. Best separations are achieved with shallow pH gradients, which are accomplished by a small pH difference between the equilibrium buffer and the elution buffer, low elution buffer concentration relative to the capacity of the ion exchanger, or a comparatively long separation column. It is essential that the salt strength of the eluting buffer is kept low, so that conventional ion-exchange elution by salt displacement is kept at a minimum. Resolution down to 0.01 pI unit differences can be achieved with commercial high-performance chromatofocusing (HPCF) media. A diagram of the gradients developed along an HPCF column during elution with a polybuffer is shown in Figure 44.

Chromatofocusing is one of the mildest of the separation techniques based on pH gradients, due to the fact that proteins are kept in a buffering environment and are not exposed to extreme pHs during the run. In this lies also a risk of aggregation or precipitation of proteins on the column, because the protein surface charge at pI is very low, and the colloidal stability of the biomacromolecular solute is hence at its lowest. However, compared to isoelectric focusing, chromatofocusing provides good possibilities of using additives to prevent protein aggregation. Urea, glycerol, ethylene glycol, zwitterionic components, and nonionic detergents can be added at high to moderate concentrations, whereas ionic additives have to be limited to a total concentration of 20–30 mM to avoid salt-induced elution. Another advantageous property of chromatofocusing is high capacity, since a large fraction of the column is used concurrently in the separation process. The separation efficiency is comparable to IEC, but HPCF can be done in shorter time on comparably sized materials.

The columns used for separation are either purposely synthesized to contain a mixture of tertiary amine and quaternary ammonium groups, or anion-exchange columns based on polyethyleneimine. Establishment of chromatofocusing as a high-performance separation technique was done by Hutchens et al. who used PEI-functionalized silica anion exchangers for analytical and preparative separation of estrogen receptor isoforms at good resolution and recovery. Coincidentally, Fagerstam et al. were working with polymer-based mixed strong/weak anion exchangers for fast high-resolution chromatofocusing of human serum proteins, and for studying protein microheterogeneity. Chromatofocusing does not necessarily have to be carried out on anion exchangers. Monkarsh et al. used, for example, a preparative strong cation-exchange sulfopropyl silica column in a quasichromatofocusing set-up with a gradient of acetate/phosphate buffers at increasing pH to resolve two 154-amino-acid fragments of recombinant human interleukin-1α differing by deamidation of one Asn (pI 5.1 and 5.3, respectively). In this 75 mL min⁻¹ eluent flow rate preparative separation, the use of inexpensive buffer components represents a significant saving.

Figure 44 Diagram of the evolution of the mobile and stationary phase pH gradients in chromatofocusing at a starting pH of 10 and a focusing buffer of pH 8. Each curve in (a) represent a gradient inside the column after the stated numbers of eluent aliquots have been pumped. The intersection of these curves with column section 10 (the bottom of the diagram, representing the column outlet) is used to construct the pH profile at the column outlet, as shown in (b). The peak shown as a hatched curve on (b) depicts a protein with pI (i.e. elution pH) 9. (Reproduced from L.A. Sluyterman, J. Wijdeness, J. Chromatogr., 150, 19 (1978) by permission of Elsevier Science B.V.)
were strongly influenced by the p
columns. Gradients were indeed formed, but their shapes

5.7 Mixed-mode Interactions in the Chromatography of
Biomolecules
Due to their heterogeneous nature, biological macro-
olecules rarely behave in a chromatographic system as
if their retention was controlled by a single separation
mode, for which the partitioning between the mobile and
stationary phase is expected to change monotonically as
a function of changes in the concentration of displacing
agent. In reality, the retention is governed to a large extent
by factors related to mobile phase interactions, such as
conformation changes, precipitation, and ion pair forma-
tion. Examples of unintentional multimodality and ways
to circumvent this have been discussed in the section on
SEC, where enthalpic interaction should be completely
avoided, and in HPLAC, where the biospecific interac-
tions should ideally be the only retentive mechanism in
operation. The extent of multimodal interaction depends
both on the separation mode and on the nature of the
solute, and will often result in concave dependencies of
retention on the displacer concentration, as illustrated in
Figure 46.

These curves illustrate that minimum retention is only
obtained in a certain range of displacer concentration. At
concentrations below this point, retention is determined
over polybuffers. Carboxylic acid weak cation exchangers
are also common.

As just hinted, the main drawback of chromatofo-
cusing has been the expensive polyampholyte eluents
and special columns that are marketed as a package
solution. Furthermore, oligomeric ampholytes are not
unproblematic, and unexpected and unwanted interac-
tions have been observed with some protein separations
(for a review see Hutchens
). Efforts have therefore
been made ever since the early days of chromatofocusing
to substitute the oligobuffers with simpler buffering com-
ponents and to use conventional ion-exchange columns
for chromatofocusing. Hearn and Lyttle
 were among
the first to evaluate common amphoteric and nonampho-
teric buffers in mixtures as development solutions for
chromatofocusing on weak anion and cation-exchange
columns. Gradients were indeed formed, but their shapes
were strongly influenced by the pK_a values of the individ-
ual buffer components and did not describe the desired
smooth and linear pH changes as a function of elu-
tion volume. This work was followed up by Hutchens
et al., who developed
 and applied
 several multi-
buffer systems containing up to 34 different buffering
substances, and were able to achieve practically linear
gradients through the nearly continuous distribution in
buffer pK_a, from pH 3.5 to 8.1.

All these studies have been based on internal pH
gradient formation, i.e. the isocratic elution buffer and
the weak ion-exchange resin are titrated by each other to
produce pH gradients both in the mobile phase and on
the resin. Results presented by Liu and Anderson
 show
that the pH gradient elution technique (termed external
pH gradient formation by Sluyterman and Elgersma
) can produce linear gradients at the column exit with a
weak anion-exchange column using only a few buffer
components. Frey et al.
 developed optimized buffer
systems which did not require a buffering weak anion-
exchange resin to form a retained pH gradient, and
also showed that they could be used for generating
quasilinear internal gradients with weak anion-exchange
materials
(Figure 45).

Linear gradients are necessary when the sample
contains many components that are to be separated but,
in preparative chromatofocusing, the desired separation
can often be achieved with a buffer system showing a few
distinct transitions in the right pH intervals. This can also
alleviate problems with tailing peaks. Such step gradients
can be produced by an internal pH gradient formation
with few retained buffer components on a strong ion
exchanger.

A practical guide to chromatofocusing has been written
by Li and Hutchens. Hutchens has also discussed the
theory and applications of chromatofocusing, and listed
commercially available stationary phases.

![Figure 45 Separation of horse myoglobin and bovine hemo-
globin on a PBE 94 column presaturated with 0.02 M DEA at
pH 9. The eluent was a mixture of 20 mM DEA, 2 mM TRIS and
4 mM imidazole, pH 7, at 0.75 mL min^-1 flow rate. (Reproduced

by the eluent strength in a conventional sense, as set forth in Equations (18–20). The increase in retention beyond the minimum is due mainly to interactions taking place in the mobile phase, resulting in aggregation of the solutes and their precipitation on the stationary phase. In reality, most biomolecule separations are therefore achieved by means of mixed partitioning and precipitation chromatography. The shapes of the four curves in Figure 46 are explained as follows.\(^\text{81}\) Shape A is typical of small polar peptides separated under RP or ion-exchange conditions, and is characterized by a shallow shape according to Equation (18) or (19). The plot has a relatively small \(k'\) value as the displacer concentration approaches zero. Retention of these compounds resembles that of small molecules, which can usually be separated isocratically over a wide range of eluent concentrations. Shape B is typical for many polypeptides and fibrous and globular proteins in RPHPLC and in HIC, as well as for most separations in IEC. The most salient feature of shape B is the narrow elution range, which efficiently precludes isocratic elution and makes the separation sensitive to the sample volume and matrix. The retention plot of curve C also exhibits a shallow dependency on concentration, similar to curve A but with a substantially higher value of \(\log k'\) at the minimum. The shallow flanks are indicative of a low number of contact points, each having a strong interaction. Curves of type C are typical of hydrophobic peptides under RP conditions, certain proteins in IEC, and some HPLAC and HIC schemes. The most problematic case in represented by shape D, wherein the minimum is sharp and located at high \(k'\) value. Therefore, the elution is difficult and low recoveries can be expected. This behavior is characteristic of many membrane proteins in RPHPLC and IEC, and their separation in RPHPLC may require addition of zwitterion pairing agents or detergents in IEC.

If gradient elution is used under sorption conditions described by curves B or D, good recoveries call for the use of relatively shallow gradients, as the solute is capable of traversing the column only within the gradient segment where its retention is at its lowest. If the eluent composition is changing too rapidly, the solute will simply be trapped by the flanks on either side of the eluent concentration of minimum retention, as it is overtaken by the rapidly changing gradient. This will effectively reattach the protein to the stationary phase before it has a chance of being eluted. For that reason, the separation chemistry should be chosen so that \(k'\) at minimum retention is unity or less. Once the optimal concentration has been found, recovery can be further improved by applying a more shallow gradient or an isocratic plateau around the critical peak. With Figure 46 fresh in mind, it should be noted that separations showing minima in retention versus eluent strength provide two possibilities of gradient elution: in the conventional fashion, i.e. by increasing the eluent strength (which means increasing eluent concentration except in HIC); and by a retrogradient starting from the opposite eluent composition.\(^\text{81}\)

Mixed-mode interactions have been intentionally exploited in order to establish unique selectivities.\(^\text{646}\) For instance, Mant et al.\(^\text{223,224,647–649}\) have used cation exchangers with hydrophilic supports, operated with organic solvents and salt as eluents, to radically alter resolution between peptides on a single stationary phase (Figure 47). Hirata et al.\(^\text{650}\) obtained unique selectivities for peptides on a poly(vinyl alcohol) column with residual carboxylic groups using aqueous acetonitrile as eluent. Floyd and Hartwick used a hydrophobic ion exchanger to separate oligonucleotides in mixed mode,\(^\text{651}\) and also presented a review of mixed-mode interactions for separation of biomolecules.\(^\text{652}\)
Multidimensional Chromatography – Coupled Column Systems

As mentioned above, an orthogonality in separation dimensions is usually necessary to achieve good separations of complex mixtures. Furthermore, as proteins may be thermodynamically unstable but kinetically stable to the chromatographic conditions, separation time and manual handling of solutes are factors working against good overall recoveries. Coupling several separation steps together in a multidimensional system is therefore rational in the separation of biomacromolecules. The distinction between multidimensional and multimode chromatography is sometimes confusing. Multimode chromatography is based on the use of a single separation material with more than one separation principle in operation, a mixture of sorbents in the same column, or columns with different separation dimensions plumbed tandem and flushed by the same eluent. Multidimensional chromatography involves the sequential use of columns with different selectivities in separate runs, operated with a heart-cut or a flush technique to transfer a select portion of the compounds eluting from the first column into the second separation step, a concept that is described by Regnier and Huang.

As opposed to small molecules, where quite incompatible solvents and separation materials have to be used in the different separation steps required to achieve orthogonal selectivities, it should be more facile to couple separation techniques for biomacromolecules because most separations are carried out in fully aqueous eluents. However, whereas coupled-column techniques are frequently used in, for instance, environmental HPLC analyses, surprisingly few automated multidimensional HPLC systems have been described for separation of biomacromolecules. A couple of recent examples are coupling of size-exclusion and anion-exchange chromatography in the analysis of poly- and oligosaccharides, and a process application utilizing an immunosorbent with immobilized protein A connected in series with a quaternary ammonium anion exchanger. An automated system has also been demonstrated for protein primary structure determination, comprising immunoaffinity chromatography, automatic buffer exchange, proteolysis with immobilized trypsin, on-line concentration/desalting, and microbore LC/MS. A few more examples are given in the peptides section.

Timing of eluent transfer to the second column is critical in multidimensional chromatography. It requires experimentally determined retention times and a dedicated instrumentation with exact timing and low dead volume values, and quite complex systems have been designed for use in automated purification, desalting, hydrolysis, and RPHPLC. A persisting problem is drift in retention times of the primary column due to ageing and fouling. But by exploiting the steep elution curves typical of most biological macromolecules, it is often possible to find a binary gradient composition on the first column, so that the retentions of the solutes to be transferred are altered from near infinite to practically nil. Such transitions are usually more dependent on mobile phase conditions than on the state of the separation column. This enables reproducible, efficient and nearly quantitative transfer of the solutes onto the head of the second column where the separation material and the conditions should be the cunning trap that is required to re-establish a sharp injection band. This entrapment is also favored by the U-shaped elution curves, where the minima seldom coincide for different separation chemistries. A particularly promising
field for multidimensional techniques is in combination with MS analysis. Commercial systems with such capabilities have started to emerge.

5.9 Slalom Chromatography

A rather odd separation principle, slalom chromatography,\(^{658}\) was discovered some years ago, but does not seem to have gained widespread use. Although performed on HPLC equipment, it can in a strict sense not be categorized as a chromatographic technique because the separation takes place entirely in the mobile phase with the packing acting only as a flow-perturbing element. Solutes applicable are large double-stranded DNA molecules (up to 50 kbp), which are separated by means of columns packed with spherical particles similar to those used for high-performance aqueous SEC. The obtained separation is based on molecular size, but smaller molecules are eluted ahead of larger molecules (Figure 48), which is contrary to the selectivity obtained with SEC materials. This inverted retention is due to a hydrodynamic phenomenon occurring predominantly in the mobile phase, whereby larger molecules are delayed because they find it less facile to negotiate optimal flow passages between the particles of the column packing.\(^{659}\) The technique has a slight similarity to hydrodynamic chromatography,\(^{660}\) a technique that exploits the nonhomogeneous hydrodynamic fields that exist near the packing surfaces in hydraulically driven flow systems due to the viscous forces. Selective enrichment of larger macromolecules occurs close to the stationary phase due to directed migration transverse to the flow direction, and the technique is used for the separation of high-molecular-weight synthetic polymers and other colloidal particles.

The dependence on a shear force makes the separation in slalom chromatography reliant on the flow rate of the solution acting as the hydrodynamic selector, i.e. no separation is achieved at low flow rates, with all solutes eluted in the column void volume, and the separation improves steadily as the flow rate in increased. There is also a temperature dependence opposite to normal, with better separations as the temperature is lowered.\(^{659}\) This technique thus deviates from conventional principles in chromatography in virtually all respects.

The choice of stationary phase appears to be of limited importance,\(^{659,661}\) but the separation is dependent on minimal partition interaction with the solutes. The particle size determines the molecular size window of the separation\(^{659}\) – smaller size range DNA molecules are better separated on small diameter packings, whereas larger particles provide improved resolution of large DNA molecules. The solutions used to bring about the hydrodynamic separation are comparatively low ionic strength salt solutions – either purely aqueous, or with a low admixture of acetonitrile.\(^{661}\) A chapter on slalom chromatography is included in a recently published monograph.\(^{41}\)

The principle involves accumulation of macromolecular solutes on the surface of the material, and the risk of precipitation should therefore not be neglected, although for molecules with pronounced polyelectrolyte behavior such as double-stranded DNA the risk should be small. It should also be kept in mind that at high flow, the shear forces may reach levels where very large solutes can start to fragment.\(^{662}\)

6 DETECTION TECHNIQUES

Analytical chromatographic separations would be futile unless a detector device that can provide quantitative (and preferably also qualitative) information is available for monitoring substances eluting from the column. The choice of detector is more important than it might appear at first. It should not only be sensitive enough to detect the eluted species in the required concentration interval, but also comprise an integral part of the overall selectivity of the method. Accordingly, detectors based on a variety of principles have been developed for use in HPLC, and their principles and characteristics have been covered in several monographs.\(^{663 - 666}\) A variety of often conflicting criteria determine the applicability of a detector. The sensitivity should be sufficient, with a linear response spanning the entire analyte concentration range. It should give stable signals and show a good reproducibility at a low noise level. The response should be fast and the internal volume minimal with a flow geometry optimized.

![Figure 48 Slalom chromatographic separations of λ/HindIII fragments (0, 0.1, 0.05, 0.15, 0.2, 4.4, 6.6, 9.4 and 23.1 kbp) on a Capcell-Pak C1 column. Eluents: 10 mM sodium phosphate buffer, pH 6.8, 1 mM EDTA with NaCl added to 0, 0.05, 0.1, 0.15, or 0.2 M concentration (left to right); flow rate 1.0 mL min\(^{-1}\). (Reproduced from J. Hirabayashi, K. Kasai, J. Chromatogr. A, 722, 137 (1996) by permission of Elsevier Science B.V.)](image-url)
to minimize band broadening. Low sensitivity to changes in eluent temperature and RI are important, particularly in gradient elution. When hyphenated systems are used, or when the separated compounds are collected for further analysis, it should be verified that the detector does not alter the solutes on passage through the detector. The reliability and user-friendliness, i.e., the level of expertise required to operate the detector, are also very important in real laboratory settings, so that the operator can easily identify a malfunction and understand how to correct it.

The detector should either give identical response to all solutes, or a highly selective response towards one or more classes of solutes. As mentioned, the detector is an important part of the overall selectivity optimization of an analytical separation. If the detector is sufficiently selective yet has a general response, the chromatographic separation process could in principle be disposed of, because the detector would be capable of both resolving and detecting the analytes in a non-chromatographic process. Examples of such detectors are mass spectrometers, notably matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS), described elsewhere in this encyclopedia.

Detectors are usually classified according to their response pattern as general or selective. A general response has a wide scope, as a single detector can be used to detect many different compounds, but also requires that the compounds presented to the detector are completely resolved. A distinction is often made between bulk property and solute property detectors, where a bulk property detector measures the changes in a bulk property of the eluent, such as RI, as a solute elutes. Characteristic of bulk property detectors is their low selectivity and sensitivity, but this is not always a drawback. Worse is their sensitivity to variations in eluent composition, which effectively precludes their use in gradient elution. Solute property detectors are designed to measure changes in a property expressed by the eluted solutes, but not by the eluent. By tuning the detector to a common property of the solutes, it is then possible to determine these in the presence of an eluent of changing concentration. A selective detector is usually tunable, whereby a discrimination of co-eluting compounds may be possible.

Most detectors are spectroscopic, i.e., they measure the interaction of solutes with electromagnetic radiation. Different wavelength regions provide access to different kinds of information and offer unique possibilities to tune the selectivity. Quantitative information is denser in some spectral regions, whereas other regions offer higher absorptivity and thereby better sensitivity, and freedom in the choice of solvents. These factors explain the persistent use of UV spectrophotometry, although the information density provided by electron excitation in solution is rather meagre. A universal feature of proteinaceous matter is the peptide bond, which absorbs strongly in the far UV, below 220 nm. A narrow window for general detection thus exists in the wavelength range 210–220 nm, below which noise and solvent absorption tends to become troublesome. Disulfide bonds absorb in the 250 nm region, and the aromatic side-chains of phenylalanine, tyrosine, and tryptophan absorb in the wavelength range 250–300 nm. The absorption band of nucleotide bases lies in the vicinity of 260 nm. Carbohydrates lack chromophores in the accessible UV region. When several absorption bands are available, the longer wavelength absorptivity is often weaker. However, the actual signal-to-noise ratio, as determined by the presence and variability of spurious peaks in the vicinity of the solute (chemical background noise), is usually better because nonsolutes rarely absorb UV light at long wavelengths. Furthermore, intensive low-wavelength UV radiation can cause bond dissociation and trigger other photochemical processes that alter the solutes on passage through the detector.

DADs are absorbance spectrophotometers capable of measuring the entire UV wavelength range simultaneously in real time using integrated photodiodes as sensing elements. Their price is low when considering the flexibility and the amount of information provided, and modern DADs are good alternatives to conventional single-wavelength UV detectors. There is a principal and important difference between multiwavelength DAD and conventional single-wavelength UV spectroscopic detectors, evident in Figure 49. In a single-wavelength detector, the eluate is illuminated by a single wavelength and the transmitted light is measured by a single photodetector. In order for multiwavelength detection to be feasible in a DAD, the sample has to be illuminated with light of the entire spectral range being measured (usually 190–380 nm), which means that photochemically sensitive substances are prone to undergo photochemical reactions on their passage through the detector. In a purely analytical setting this may not be troublesome, unless artifact signals are produced from irreproducible bleaching or formation of new compounds in the detector cuvette. However, photochemical processes must be considered if the separated compounds are collected for further investigations.

Fluorescence detection is based on emission of light following photoexcitation and is a native property of some biological molecules, notably polynucleotides and aromatic peptide lateral groups. Fluorescent properties can also be introduced in molecules by derivatization (see below). As opposed to spectrophotometry, where the measurement is based on log transformation of subtractively measured absorbed light, fluorescence is at low solute concentration a linear function of the solute concentration and the intensity of the incident beam. The
Figure 49 Optical and flow cell components of a single-beam diode array detector using reversed optics, meaning that all the light from the lamp passes the flow cell before reaching the wavelength-dispersive element, where it is separated into its spectral components and projected onto the photodiode array. (Reproduced by permission of Hewlett-Packard Company.)

emitted light is collected perpendicular to the excitation beam and the need to extract the signal by subtraction is thereby eliminated, enabling sensitive and selective detection. Selectivity is further enhanced as few molecules absorbing light are capable of fluorescing. A suitable entry point to this literature can be the recent review of Tao and Kennedy on laser-induced fluorescence detection in microcolumn separations.\(^\text{669}\)

Chiroptic detection based on measurement of circular dichroism (CD), i.e. the difference in absorption of the clockwise and counter-clockwise rotated vector components of a polarized light beam passing through a medium containing a chiral component, has been used for a long time in HPLC.\(^\text{670}\) The CD principle is also widely used for determining the secondary structure of proteins, because of the chirality of amino acids and the spontaneous organization of polypeptide chains in either left- and right-twisted \(\alpha\)-helices and \(\beta\)-pleated sheets, or as a random coil, producing a characteristic optical rotation and CD spectra. Thus, CD detectors can provide information on the conformation of eluted proteins.\(^\text{671}\) The main drawback of CD detectors is their limited sensitivity, which restricts their use to separations carried out on high-capacity materials, where the concentration of protein is relatively high.\(^\text{672}\)

Vibrational spectra carry more information than the electronic excitation spectra obtained in the ultraviolet/visible (UV/VIS) region. However, infrared spectroscopy detection is not a viable alternative, because the solvents used for the separation of biomacromolecules are not transparent in the infrared region. Raman spectroscopy has been used sporadically as a detection principle in HPLC. For instance, purine bases have been detected by on-line surface-enhanced Raman spectroscopy after mixing with a silver sol.\(^\text{673}\)

Modern high-field nuclear magnetic resonance (NMR) spectroscopy provides an extremely powerful tool set for characterization of biological macromolecules and their interactions. However, although direct coupling of NMR to HPLC has been successfully utilized for structural elucidation of small molecules,\(^\text{674}\) the long time required for obtaining spectra for large molecules has prevented the use of LC/NMR for on-line characterization of eluted biomacromolecules. When NMR spectroscopy is used in combination with HPLC of biomacromolecules, eluted peaks should therefore instead be collected and subjected to off-line spectroscopy.

RI detectors measure changes in the index of refraction of the eluent induced by the solute. In principle, all solutes affect the eluent RI, but the sensitivity varies, and compounds lacking absorption or other properties enabling selective detection can often be detected by RI detection. The drawback of RI is that it is a bulk property of the eluent, which makes the detector signal very sensitive to eluent composition and effectively precludes gradient elution. As the majority of all separation schemes
for biomacromolecules require changing eluent composition, RI detection is usually impossible. An exception is high-molecular-weight carbohydrates, for which separation often takes place in SEC and where the lack of chromatophores has been a persisting problem. Differential RI detection is thus still used, often hyphenated with other measurement principles. Recent developments have alleviated the temperature sensitivity and improved the detection limit substantially.\(^{675}\)

Related to RI detection, although with a radically different sensitivity and degree of sophistication, is surface plasmon resonance, a principle used in the leading biosensor system. The small biosensor detection volume makes it suitable for use as an HPLC detector,\(^{676}\) in particular in affinity chromatography.\(^ {677,678}\) This and other biospecific detection principles have been reviewed.\(^ {679}\)

Due to their size, biomacromolecules are good scatterers of light in solution, which forms the basis for the low-angle laser light scattering (LALLS) and MALLS principles that have been introduced to LC detectors in recent years. Both of these measurement principles can provide information on the molecular weight of biomolecules, thus supplementing external calibration in SEC. The additional information provided by multiple measurement angles in MALLS also provides information on the radius of gyration, so that characterization of both the molecular mass and the shape of biomacromolecules can be carried out on line.\(^ {680}\) An example of a SEC separation with MALLS and differential viscosity detection is shown above (Figure 16). A commercial detector is also available where the scattered light is measured at right angles (RALLS). This detector is combined with an RI detector and a viscosity detector based on measuring the differential pressure across a detector cell containing multiple capillaries for determining association and rheological phenomena of high polymers.

A different scattering principle is used in evaporative light scattering detection (ELSD), where the signal is based on light scattered from a dried aerosol produced by spraying the eluent into a desolvating chamber and evaporating the solvent and other eluent components. Nonvolatile solutes form microparticles that are detected in the gas phase as they pass the detection cell. The technique has become particularly popular in the separation of lipids and related substances, and for carbohydrates. An entry point to the literature can be a recent review of its use in combinatorial chemistry.\(^ {681}\)

Many electrochemical detectors exist, but the mode particularly interesting for biological macromolecules is pulsed amperometric detection (PAD),\(^ {682}\) because it is capable of detecting polar aliphatic compounds containing alcohol, amine, and thiol groups that are not easily detected by photometric or fluorimetric techniques. The PAD technique uses a pulse sequence to adsorb compounds on a platinum or gold electrode surface and then selectively oxidize the deposited compounds, followed by a cleaning sequence where adsorbed material is oxidatively removed from the surface prior to the next pulse sequence. The strongly adsorptive properties of noble metal electrodes, which are problematic under nonpulsed conditions, are thereby mastered and turned into an advantage and the PAD technique has become the preferred non-MS detection method for detecting carbohydrates.

Almost general yet highly selective, MS is close to fulfilling all requirements of an ideal detector. Its extremely high sensitivity coupled with a multitude of ionization and fragmentation techniques makes it capable of providing sufficient information to resolve the structures of complicated biological macromolecules. The ease of using a mass spectrometric detector has improved vastly, and it is now an accessible technique even outside the most sophisticated laboratories, which makes it a serious competitor to the techniques listed above. However, the cost of buying and operating an MS detector is still high compared to the alternatives. Traditional detectors will therefore still exist alongside MS for a long time where their performance is adequate. The LC/MS combination forms an extremely powerful tool for structural elucidation of biomacromolecules, a topic dealt with in other parts of this encyclopedia.

### 6.1 Labeling Reactions for Introduction of Detectable Properties

Intrinsic properties such as UV absorption, native fluorescence, or electrochemical activity form the basis of most detection schemes in HPLC and sufficient detection limits can usually be obtained with substances in their native form. However, in trace work, the sensitivity achievable by the use of intrinsic properties can be insufficient, and it may therefore be necessary to resort to derivatization, i.e. enhancing the detectability of solutes by introduction of a detectable property through chemical reactions. These reactions can be carried out either before the sample is injected (precolumn), or after the sample has been separated (postcolumn). Derivatization techniques targeting functional groups present in biomacromolecules have been described in several books.\(^ {668,669,680}\) Two recent reviews by Krull et al.\(^ {687,688}\) focus on derivatization and detection of proteins. Koller and Eckert have reviewed derivatization of peptides,\(^ {689}\) and Boppana and Miller-Stein gave an outline of pre- and postcolumn derivatization techniques for sensitive detection of peptide drugs.\(^ {690}\) A sensitive separation of peptides with ninhydrin postcolumn derivatization is shown in Figure 50.
Precolumn derivatization uses polar functional groups in the solute to attach a tag, i.e. a chromophore, a fluorophore, an electrophore, or a moiety within a characteristic fragmentation pattern in MS. The derivatized analyte is then separated and detected through the properties of the attached tag. A wide variety of labeling reagents are available, targeting amino groups, hydroxyl groups of different reactivity, carboxylic acids, keto and aldehyde groups, etc. The tags originally introduced were promoting UV absorbance, but over the years derivatization for fluorescence detection has become more common. The detection limits obtainable by fluorescence derivatization rival those obtainable in MS, so fluorescence detection may be an alternative worth considering if the added identification and structural elucidation possibilities of MS are not needed. Precolumn derivatization reagents and their break-down products usually display the detectable property, and excess reagent will therefore be visible in the detector, although eluted at a different retention time. The reagent is therefore usually added only in moderate excess relative to the target functional groups, to avoid large spurious peaks in the chromatograms. At low analyte concentrations, reaction speed will be radically decreased because both the reagent and solute are reactants in a bimolecular reaction. Ways to circumvent this are to add more reagent and remove the excess reagent by extraction, or to allow it to react with a solid carrier containing functional groups reacting with the reagent. When considering whether or not to apply a derivatization scheme, it must be taken into account that precolumn derivatization alters the retention properties of the analytes, so that existing separation schemes have to be modified. An altered retention pattern can also be the reason for carrying out a derivatization, e.g. by reversible attachment of chiral fluorescent groups or fluorescent groups capable of expressing affinity interactions. Derivatization of biopolymers is complicated by the possibility of multiple derivatization on several reactive groups, leading to multiple products from a single solute molecule. Although this carries a potential for more sensitive detection, it is likely to lead to splitting of solute peaks in the separation step. A monumental handbook of derivatization techniques for HPLC was published recently.

Postcolumn derivatization is based on separating the analytes in their native form, then subjecting them to a derivatization reaction after the sample has passed the column. This means that existing separation schemes can be used, provided the eluent is compatible with the postcolumn derivatization reaction. The reaction is carried out on line by adding one or more reagents to the eluate and allowing sufficient time for the reaction to take place before the sample is passed into the detector. Successful use of postcolumn derivatization calls for reagents acting as a precursor of the detectable property, i.e. the reagent itself should not be visible
to the detector, but be converted into a detectable moiety on reaction with specific functional groups in the solutes. As in precolumn derivatization, reaction kinetics is central and reaction time must be gained by delaying the eluent–reagent mixture on its way to the detector. Various means of accomplishing delays without excessive band broadening have been described in the literature but some deterioration of the separation efficiency is inevitable. The books referenced above provide more information on applicable techniques.

7 SAMPLE PREPARATION

General guidelines for preparing samples are difficult to give, because the diversity of biological macromolecules and the matrices in which they exist is infinite. A few key concepts are nevertheless important to convey. The most prominent feature of material derived from living organisms is biological activity, and cellular processes are characterized by a continuous reconstruction through simultaneous enzyme-catalyzed metabolic and catabolic processes. Metabolic break-down of macromolecular components by controlled enzymatic processes is a central part of a system where building units are extensively recycled and, in a living cellular system, sensitive molecules are separated from metabolic processes by membranes and other barriers. A controlled exchange of material takes place with the surrounding tissue or medium through these barriers in processes driven by energy. When the system is disturbed, it will attempt to accommodate to the changes by altering the cellular processes, and if the perturbations are sufficiently large, the system collapses and the cells will die. However, this does not mean that all processes taking place in the cell will cease, only that the pathways and the mechanisms will be different, and in the absence of added energy the metabolic processes will prevail. As the energy required to maintain order ceases to flow, components normally kept separate can come in contact.

What this dramatic account of impending chaos and disorder intends to tell is the importance of knowing the history of a sample, and to control processes that lead to alterations of samples. In general, a biological sample should be subjected to analysis as soon as possible after isolation. If this is not possible, appropriate measures should be taken to ensure that the components of interest are not subject to changes by biological or chemical processes. There are numerous ways to store a sample, and the more common are freezing and lyophilization. Both these processes will lead to disruption of membranes in tissue samples, so that most components will be in contact with each other when the sample is thawed or rehydrated. Such samples are therefore particularly prone to alterations. Of particular concern are proteolytic enzymes, which exist in all biological systems. If left to operate on a cell suspension, they will rapidly lead to significant alterations. Other enzymatic processes can also cause changes to the samples. Obviously, this breakdown or alteration will largely cease if the analytes are separated from the enzymes responsible for catalyzing the changes, or if these enzymes are inhibited. Metal-complexing agents such as EDTA and EGTA (ethyleneglycol bis(amoindoethyl)tetraacetic acid) are widely used and protease inhibitors are available singly or in mixtures for adding to samples in order to prevent break-down. Hassel et al. recently published a study of ways to eliminate unwanted proteolysis during extraction of proteins from protease-rich tissue, and came up with a rather complicated mixture of inhibitors and metal-complexing agents. However, this should only be regarded as a first aid, as addition of reagents complicates the matrix and addition of foreign biological material compromises the integrity of the sample. Also, protection by recognized synthetic or biological protease inhibitors cannot be entirely relied upon, as is evident from accounts in the literature. The key rule is to keep the samples on ice, and to initiate the preliminary sample clean-up steps as soon as possible, in order to separate deleterious components from the analytes. Keeping samples cold also helps maintain the biological activity of sensitive proteins that may be rapidly denatured when the cellular environment is disrupted. Detergents may be needed to get and keep solutes in solution, such as use of the mild nondenaturing detergent Triton X-114 as a phase-partitioning agent in the purification of plant proteins. Micelles may also be valuable, as in the extraction of hydrophobic peptides. Partitioning in aqueous two-phase systems is a batch-operated soft-separation process for cells, organelles, and membranes that can be used as a sample preparation step for high-performance separation.

Reviews have been published on sample preparation and column regeneration in protein separations, sample preparation and separation of food-derived peptides, the use of solid-phase extraction for preparation of catecholamines and biologically active peptides, on hydrolysis and amino-acid composition analysis of proteins, and on enzymatic digestion of DNA for determination of nucleotide composition. Solid-phase extraction on a weak cation exchanger has for example been used to quantitatively extract and concentrate peptides from plasma samples with simultaneous removal of endogenous interferents.

Other processes leading to alterations of a sample are changes in the redox state and the influence of light. Although the latter factor is simple to control, it is more difficult to control the redox potential in a sample,
which can have significant impact on thiols, disulfide bridges, conjugated phenols, and other easily oxidized or reduced moieties in biological macromolecules. Addition of 2-mercaptoethanol or dithiothreitol is common in order to prevent oxidation of methionine\(^{708}\) or to break disulfide bonds in difficult-to-extract proteins, such as hair.\(^{709}\) The final culprit is surface adsorption of trace amounts of biopolymers, which should be controlled by the same intuition that guides the choice of stationary phases and eluents in LC.

### 8 PREFERRED SEPARATION TECHNIQUES FOR DIFFERENT CLASSES OF BIOMACROMOLECULES

Descriptions of the various techniques presented above have listed numerous examples of separations for each separation mode. The other dimension into this vast field is application-oriented. The exceptional variation in biological macromolecules and the size of the field make it impossible to cover applications except in summary, and the best way is to guide the reader to recent relevant reviews.

#### 8.1 Oligonucleotides and Polynucleotides

Separation of polynucleotides is nowadays a stronghold of electrophoretic separation techniques, the most important being Southern and Northern analysis,\(^{710}\) and capillary gel or zone electrophoresis,\(^{711,712}\) However, liquid chromatographic techniques have been important in nucleic acid research, often in combination with electrophoretic techniques,\(^{713}\) and are still widely used for clean-up, sample preparation, and for analytical separations.\(^{714}\) Polymeric nucleic acids are linear polymers, where the chains are held together by phosphodiester links between the 3' and 5' hydroxy groups in the (deoxy)riboses of adjacent nucleotides. The negative charge comes from the phosphodiester links, but there are also positive charges from some of the pyrimidine or purine bases of the nucleotides. In a homopolymer, the charge will increase linearly with length but, as natural nucleic acids are heteropolymers, charge cannot be directly correlated to the length of the polynucleic acid. Separations are also complicated by the formation of complexes between nucleic acids. These interactions can take the form of hair-pin turns within the same molecule, bonding between adjacent chains, or association to hydrophobic sample components.

Both hydrogen bonding and hydrophobic forces are important in the intermolecular interactions of nucleic acids. Presence of water diminishes the importance of hydrogen bonds, but in oligonucleotides the bases are stacked because of hydrophobic \(\pi\)-electron interactions between the aromatic bases. This stacking prevents water from accessing the hydrogen bonding sites of the bases, and strengthens the interchain binding. The hydrophobic interactions can be broken by solvents, so that water is provided a better access. Water then competes with the bases for the available hydrogen bonding sites, which weakens the bonding between base pairs. Many RP-HPLC solvents are capable of mediating this breaking of hydrogen bonds. Because of this dual mechanism, these solvents can be used not only to control the retention in RP-HPLC, but also to increase the retention in anion-exchange chromatography of oligonucleotides. Interchain hydrogen bonding is furthermore affected by the structure of water, whereby chaotropic salts tend to break up hydrogen bonding, whereas cosmotropic salts increase the structure and should be avoided in the separation of “sticky” oligonucleotides. Increased temperature also promotes dissociation of bonds between oligonucleotide chains. Applicable HPLC separation schemes are consequently based on hydrophobic interactions (RP), ionic interactions (anion exchange), and hydrophilic interaction. Metal systems should be avoided because phosphate groups bind strongly to metals. Addition of phosphate to the buffer will decrease interactions with metals. A separation of a DNA digest by anion exchange is shown in Figure 51.

Retention in RP-HPLC is due to the aromatic character of the bases, and can be altered by the addition of an alkylamine ion pair reagent to the eluent, effectively transforming the separation into a mixed-mode reversed-phase ion-exchange chromatography (RPIEC). Separation materials with shorter alkyl chains are often preferred over octadecyl silica, as the retention with the latter phases tends to be high. Except for very short oligonucleotides, elution must be done with gradients. In anion-exchange chromatography, retention is controlled by salt concentration, pH, and admixture of solvent, which is recommended to break hydrophobic interactions. Because the charge is increasing rapidly with increasing size, elution has also here to be accomplished by gradients. Contrary to RP, retention in anion chromatography increases with solvent concentration.\(^{716}\)

A comprehensive coverage of nucleic acid separations was the subject of a special issue of *Journal of Chromatography* (Vol. 806:1). It is significant that a majority of the papers dealt with electrophoretic or other nonchromatographic techniques, but HPLC is nevertheless being used. Two of the chromatography papers were reviews and treated the use of micropellicular anion-exchange and ion-pair RP stationary phases and optimization of gradient elution parameters in the separation of double stranded DNA\(^{715}\) (includes a table comparing anion-exchange and ion-pair RP DNA separations), and displacement chromatography in the purification of
synthetic oligonucleotides and nucleic acids.\(^{717}\) The analysis of DNA adducts by capillary HPLC and CE coupled to MS was reviewed by Apruzzese and Vouros,\(^{718}\) who discussed the entire analysis chain with extraction, hydrolysis, enzymatic digestion, and solid-phase extraction or HPLC as sample preparation steps. The use of LC/MS for the characterization of nucleosides, nucleotides, modified nucleotides, oligonucleotides and DNA adducts was reviewed by Esmans et al.,\(^{719}\) collating the procedures for the analysis of oligonucleotides in a diagram. The preferred technique is HPLC with electrospray MS. Techniques for the detection of damage to DNA were reviewed by Cadet and Weinfeld\(^{720}\) and by Frenkel and by Klein,\(^{721}\) and the use of HPLC for recognizing covalent modifications to nucleic acid by anticancer drugs was reviewed by Cummings et al.\(^{722}\)

Size-dependent chromatographic separation of nucleic acids, in particular slalom chromatography, was reviewed by Kasai,\(^{658}\) and the use of nucleic acid polymers immobilized on solid supports for affinity chromatographic isolation of polynucleotides and polynucleotide binding proteins was the subject of a review by Jarrett.\(^{472}\)

The use of three acrylate-based SEC columns with different molecular weight cut-offs connected in series was described by Franek and Koutnik to separate oligonucleosomal DNA fragments from apoptotic animal cells with molar ammonium acetate as eluent.\(^{723}\) Itoh et al. used a fluoroalkyl silica that was converted into a mixed-mode sorbent by treatment with triethylmethylammonium chloride for separation of various nucleic acids by gradient elution with either an acetonitrile solvent gradient or a perchlorate salt gradient.\(^{724}\) Good separations could be obtained by both elution mechanisms. The mixed mode could be used for separations of up to 40-mer oligodeoxynucleotides, and for oligoctydylates, oligodeoxynucleotides, and t-RNA. Chromatography on strong anion-exchange columns has been used for the preparative purification of supercoiled plasmid DNA.\(^{595}\) Ion-pair HPLC could resolve three components in a reverse transcriptase chain reaction product, whereas only two components were detected by agarose gel electrophoresis.\(^{725}\) An example of RP separations of DNA digests is shown in Figure 52.

Transfer-RNA has been separated by gradient elution on hydroxyapatite, and it was found that increased pH caused a stronger bonding of t-RNA to the stationary phase, a retention dependence opposite to proteins.\(^{613}\) A mixed-mode separation on aminopropyl silica modified with alkyl groups, mainly according to the HIC mode, has also been used for t-RNA.\(^{726,727}\) High-molecular-weight RNA has also been separated on hydroxyapatite following dissolution in guanidinium isothiocyanate.\(^{614}\)

A way to accomplish 5'-aminoalkyl labeling of DNA oligomers through N-hydroxysuccinimide ester activation and separation of the resulting derivatives was described by Wang et al.\(^{728}\) Mixed-mode separation of nucleic acids has also been reviewed.\(^{729}\)

### 8.2 Peptides

Peptides are small proteinaceous compounds, ubiquitous in living creatures and in the natural environment.
When actively produced by organisms, peptides tend to have highly specific tasks and their biological activity is usually expressed at very low concentrations. Isolation of peptides is therefore important in biosciences, both for analytical purposes and as preparative steps in biological and biomedical research. Because of their potential activity, it is also essential that peptides synthesized for research or therapeutic use are efficiently purified before being used in biological systems, a task often accomplished by preparative HPLC. Peptide separation is furthermore a central part of peptide mapping schemes (Figure 53) for elucidating protein structures.

The distinction between a peptide and a protein is somewhat arbitrary, but it is common to refer to amino acid sequences with 50 residues or less as peptides. The properties differ widely in this range – dipeptides are small molecules and behave chromatographically as such, with shallow retention curves and retention more or less directly related to the properties of the constituent amino acids. Large peptides with $M_W$ of several thousand daltons differ little from proteins in their chromatographic behavior and follow the multiple interaction mechanisms outlined in the introduction. Under favorable conditions, peptides lack secondary structure such as $\alpha$-helices up to a size of about 15 amino acids. When peptides exceed this length, the likelihood of secondary and tertiary structure increases and, towards the upper size limit, peptide chains are prone to fold in order to internalize side-chains of low polarity. This has a pronounced effect.
Table 8 Summary of HPLC separation techniques commonly used to separate peptides

<table>
<thead>
<tr>
<th>Separation mode</th>
<th>Use</th>
<th>Typical eluents</th>
</tr>
</thead>
<tbody>
<tr>
<td>SEC</td>
<td>First separation step, isolation of peptides from proteins and other large molecules. Columns with pores separating from 100 to 7000 Da are available for analytical separations.</td>
<td>Water with the addition of buffer and salt at a concentration sufficiently high to suppress adsorption tendencies due to residual ionic charge on the stationary phase.</td>
</tr>
<tr>
<td>IEC</td>
<td>Gaining in popularity because small changes in pH can give large changes in selectivity. Ion exchange materials with high separation efficiency have also become available.</td>
<td>Cation-exchange mode is favored, at least with silica-based materials. Elution can be carried out by salt or pH gradients.</td>
</tr>
<tr>
<td>RPHPLC</td>
<td>The most popular technique because of the high separation efficiency, the wide scope, and the relative stability of peptides, compared with proteins.</td>
<td>Gradients of water-miscible organic solvents (acetonitrile is often preferred) in acidic buffers. The buffer anion can have an effect on selectivity.</td>

on the apparent hydrophobicity and the dissociation constants of ionizable side-chains in the native state. The presence of disulfide bridges also contributes to conformational changes, and depends on the oxidation state of the peptide. All factors leading to alterations in conformation must be considered and brought under control when a method is developed, because they may have a large impact on the chromatographic behavior of a peptide.\(^{(125)}\)

Separation schemes for peptides are often complex, especially when the analyte exists in a biological matrix. Combinations of chromatographic techniques with orthogonal separation dimensions are therefore regularly employed. Because of the relatively low molecular weight and reasonable stability of peptides, a variety of HPLC subtechniques which would lead to irreversible sorption or denaturation of larger biomacromolecules may be applicable. The most popular separation modes are SEC, IEC, and RPHPLC. The initial separation steps usually aim at isolating the molecular weight fraction of interest from proteins and low \(M_\text{W}\) matrix components. Final separations of the peptide fraction are then carried out with techniques that capitalize on differences in hydrophobicity or net ionic charge. Gel electrophoresis and capillary zone electrophoresis (CZE) are useful for verifying the purity of separated peptides, as their separation principle based on differential migration in electric fields is markedly different from chromatographic partitioning. Table 8 summarizes the most important HPLC techniques used in the separation of peptides.

As can be inferred from their biological significance, separation of peptides has been the subject of numerous monographs\(^{(73,735–738)}\) and a large number of review articles, of which a select number are referred to below. Recent practical reviews have been written by Mant and Hodges,\(^{(125)}\) and by Lundell.\(^{(739)}\)

SEC is often used as the first step in a multistep peptide separation protocol or for separation of peptides from proteins. The most frequently used columns are silica columns with pore sizes of 60–150 \(\text{Å}\). These columns are designed for SEC of proteins and the molecular weight range is thus unfavorable for separation of peptides. Polymer-based columns designed for optimal separation of the molecular weight range 100–7000 Da are commercially available and have been successfully used in the SEC separation of peptides\(^{(740)}\) (Figure 54). The general precautions outlined above apply to peptides. Self-association and interaction with other biomacromolecular solutes can also affect their separation. The use of denaturing conditions,
such as by the addition of urea, may therefore be necessary to ascertain that the peptides are monomeric.

The theoretical and practical aspects of high-performance SEC of peptides was recently reviewed by Irvine.\(^{741}\)

RPHPLC of peptides is typically run on silica columns with linear alkyl functional groups (C\(_4\) to C\(_{18}\)) of 100–300 Å pore size, with gradients of 2-propanol, acetonitrile or methanol. Some TFA or another acid (see above) is added to the eluent in order to suppress the dissociation of surface silanols, and to accomplish an ion pairing with basic amino acid side-chains. Due to the reasons outlined under mixed-mode interactions above, gradient parameters may be critical to success. A gradient should always start from a low concentration of organic modifier, not pure water, because the layer of alkyl chains on RP stationary phases can collapse in entirely aqueous eluents. The best separations are usually obtained with relatively shallow, linear gradients. The final concentration of organic modifier is typically between 50% and 100%, which means that the solubility of ionic mobile phase additives should be checked at the highest modifier concentration. Extremely hydrophobic peptides may require special eluents and solvents.\(^{742}\)

The column temperature can be used to fine tune the retention through temperature-induced conformation changes of peptides in contact with the stationary phase. A slightly increased temperature can also improve the separation efficiency because the eluent viscosity decreases, affecting the diffusion coefficients positively. A comparison of RPHPLC and transient isotachophoretic CZE for the determination of peptides in plasma has been published.\(^{707}\) The related but softer separation principle of HIC is useful for separation of larger peptides, whose secondary structure is creating problems in RPHPLC, or if denaturation is an issue.\(^{99}\)

Synthetic peptides are regularly purified by RPHPLC (Figure 55), although other techniques are also used, such as cation exchange,\(^{161,743,744}\) mixed-mode HIC/cation exchange,\(^{224,647–649}\) ion pair chromatography,\(^{745}\) and IMAC,\(^{495}\) specifically for isolating peptides with metal-binding N-terminal amino acids (His, Trp, or Cys).\(^{746}\)

The conventional eluent for RPHPLC of peptides is an aqueous acetonitrile gradient acidified with TFA. Addition of perchlorate ions to the mobile phase was recently demonstrated by Sereda et al.\(^{236}\) to have a pronounced effect on the retention of synthetic amphiphilic α-helical and nonhelical peptides in C\(_8\) RPHPLC, where phosphoric acid was used to acidify an acetonitrile gradient. The general trend seen on adding perchlorate was an increased retention, accompanied by changes in selectivity. These effects were ascribed to ion-pair formation between amino acids with a positively charged side-chain and the perchlorate ions, which was also confirmed by calculations. The selectivity of the eluent containing aqueous phosphoric acid–perchlorate–acetonitrile was also markedly different from aqueous acetonitrile–TFA. Addition of chaotropic anions to the eluent thus provides a tool for altering the retention compared to that obtained with acetonitrile–TFA gradients. Chiral separations\(^{211,691}\) may be required for determination of the enantiomeric purity of peptides in the pharmaceutical, alimentary, and agricultural industry.

An entire volume of Analytica Chimica Acta was recently devoted to the chromatography of peptides. Among the reviews presented was a survey by Štulik et al. of RP, HIC, SEC, IEC, affinity, and CSP for peptide analysis by HPLC.\(^{95}\) The paper contains an outline of how the chromatographic behavior of a peptide is influenced by its physicochemical properties and lists a number of manufacturers providing columns with different chemistries for separation of peptides. Characterization and purification of peptides by high-performance strong cation-exchange chromatography was reviewed by Crimmins.\(^{569}\) A commonly used stationary phase is sulfoethyl aspartamide. Separations are carried out at an acidic pH to promote the cationic character of basic groups. Among the synthetic analytes used as examples are N-terminally blocked and disulfide linked peptides. Separation of model peptides subjected to limited proteolysis was reviewed by Rholam and Cohen,\(^{747}\) with particular emphasis on cleaving site structure in order to establish models for peptide hormone catabolism. Monitoring proline-specific endo- and exo-peptidase activity by HPLC assays was reviewed by Harada,\(^{234}\) Characterization of human hemoglobins by the differences in their polypeptide chains was reviewed by Huismann,\(^{748}\) discussing separations by cation exchange and RPHPLC on short alkyl chain columns. Meriluoto\(^{235}\) summarized the separation of microcystins and nodularins, classes of cyclic...
hepatotoxic peptides with tumor-promoting properties produced by water-blooming cyanobacteria. Emphasis is placed on the conditions for extraction from different types of sample matrices, separation by anion exchange, and by RPHPLC with conventional and internal surface materials. A comparison is also made with other methods for determination of these peptides. A strategy for screening of combinatorial peptide libraries was reviewed by Hammond, focusing on peptide sequences immobilized on a carrier and used as affinity ligands in highly specific purification schemes for proteins. The interaction of the target amino acid sequence FLLVPL with fibrinogen (blood clotting Factor I) was described and its use for purification of the protein was discussed.

Neuropeptide separation has been treated in several recent reviews. Rissler addressed sample preparation, separation, and determination of low levels of peptides related to substance P, an undecapeptide involved in the transmission of pain. Hurst and Zagon reviewed the sample preparation, separation and detection of enkephalins. Desiderio presented a review of separation and detection of endogenous neuropeptides in various biological tissues and fluids, and Desiderio and Zhu reviewed the sample collection, SPE clean-up and HPLC separation in the determination of Met-enkephalin and β-endorphin from pituitary gland tissue (Figure 55). Both papers discussed radioimmunoassay (RIA) and tandem MS, among other detection techniques, and concluded that tandem mass spectrometry (MS/MS) was superior for detecting these peptides.

Multidimensional separations are required to separate highly complex peptide mixtures. An LC/LC/MS system for mapping fragments from proteolytic digests was thus constructed by Jorgenson et al., based on conventional diameter analytical HPLC columns. The first separation dimension was by SEC, using six 30-cm long columns in series with 0.1% aqueous TFA as the mobile phase. Fractions from this column train were transferred to an RPHPLC separation step using two columns packed with nonporous C18 modified silica with an aqueous acetonitrile gradient containing 0.05% TFA (Figure 56). Peptide fragments from ovalbumin and BSA were separated with this system and identified by electrospray MS. Another LC/LC/MS technique (cation exchange followed by RP) was also found to be promising for the separation and identification of undigested proteins.

Coupling HPLC with electrophoretic separation techniques adds yet another separation dimension because of the radically different separation principle of CE compared to interaction chromatography. Moore and Jorgenson separated fluorescein isothiocyanate (FITC)-tagged peptide fragments from trypsin digests of hen

**Figure 56** Single coupled-column RPHPLC chromatogram extracted from a SEC separation (retention time interval 90–94 min), showing separation of tryptic peptides as detected at 215 nm. (Reproduced from G.J. Opticek et al., *Anal. Chem.*, 69, 2287 (1997) by permission of American Chemical Society.)
ovalbumin by size exclusion on a hydrophilic macroporous 2-hydroxyethyl methacrylate/ethylene dimethacrylate (HEMA/EDMA) copolymer column, using 85% methanol–100 mM ammonium acetate as mobile phase at low flow rates. The fragments eluted from the SEC column were sampled repetitively on-line and subjected to separation on a narrow bore 5-µm C8 column with a fast aqueous acetonitrile gradient. The exit of this column was in turn linked to a vertical fused-silica CZE capillary, onto which sampling was triggered by a high speed optical gating injection system to obtain a comprehensive three-dimensional peptide separation. Another automated application of HPLC is in the chromatography-based assay of enzyme activities, reviewed by Lambeth and Muñonen. The potential of multiple separation techniques in combination with selective and sensitive detection is large, but the design and operation of multidimensional systems requires considerable expertise and it is not yet a feasible technique for most analytical laboratories. It should also be mentioned that matrix-assisted laser desorption/ionization (MALDI) and direct injection electrospray MS are nonchromatographic separation techniques that can be favorably used for peptide samples in relatively sparse matrices.

Detection-oriented techniques for identification and determination of peptides containing arginine, cysteine, proline, tryptophan, or tyrosine residues were reviewed by Cui et al. A number of selective derivatization reagents were discussed, targeting each residue, and electrochemical (tyrosine-containing peptides), UV, and fluorimetric detection is used to identify the residues based on the properties introduced by the reagents.

8.3 Proteins

Chromatographic separation of proteins can take place either by interaction or by size exclusion. Interaction chromatography is based on contact between the amino acid residues at the outer surface of the protein and the stationary phase, resulting in interactions whose strength is adjusted by varying the mobile phase conditions. Proteins differ in stability and their conformation can be significantly altered during separation, with changes in their surface properties as result. Which residues will be exposed is of course determined by the basic structural features of the protein, but also to a large extent by the chromatographic conditions. The factors important for controlling the protein structure and hence the exposed surfaces during separation are the stationary phase (the nature of the ligands and their density, the chemical nature and porous properties of the matrix), the mobile phase composition (pH, solvents, concentration and type of added salts or nonionic agents affecting the water structure, presence of detergents or other additives), and also physical factors (temperature and flow rate). A general strategy for the separation of proteins is therefore difficult to formulate.

The best guidance is obtained by gathering as much information as possible on the proteins to be separated. Amino acid sequence, chemical nature, size, helicity and three-dimensional structure, and knowledge of the biological function are factors that can be useful in selecting an optimal separation scheme. If the proteins have been characterized, data are likely to be present in databases that are freely available on the Internet. One such database, which is referenced here in spite of the volatile nature of the Internet, is the ExPaSy Molecular Biology Server. The data that can be collected or computed on this server can be very useful for designing protein separations. Among the modules available is a huge database of protein sequences, families and domains, two-dimensional polyacrylamide gel electrophoresis data, three-dimensional images of proteins and other biological macromolecules, and enzyme nomenclature. Tools for protein identification and characterization, facilities for similarity, pattern and profile searches, primary structure analysis and secondary structure prediction, and tertiary structure and transmembrane region detection also exist on this server. Calculations can be done from the database entries, or from user-entered primary structures. ExPaSy also provides links to a large number of other servers with additional databases and computational facilities.

Advanced protein separation techniques was the topic of a recent review issue of Journal of Chromatography, including overviews of new packing materials, nonporous sorbents, permeable packings, and protein interactions at sorbent interfaces. Strategies were reviewed for separation of recombinant proteins, sensitive enzymes, modified hemoglobins, lipoproteins, glycoproteins, glycated and carbonylated proteins, and the isolation of allergens. Special techniques such as labeling reactions and the studies of drug–protein interactions were also part of this issue. A number of books are also devoted to chromatography of proteins. A recent monograph by Sadana deals with the mechanisms for different bioseparation processes and how they affect protein stability. The molecular basis of surface activity and protein adsorption is discussed and strategies for avoiding inactivation are outlined. Oscarsson has reviewed the factors leading to partitioning of biomacromolecules to sorbents, with particular attention to protein–surface interactions, and describes a scanning probe microscopy technique for studying such interactions at the nanometer level. Beeckmans has reviewed the use of chromatographic techniques for studying protein–protein interactions, and provides an extensive practical section on support activation and immobilization.
8.3.1 Membrane Proteins

The group of proteins associated with cellular membranes differ in their way of attaching to the lipid bilayer. Integral membrane proteins are attached either by covalently bound lipid chains, or by having a consecutive sequence of amino acids with low-polarity side-chains sufficiently long to extend through the lipid membrane, whereas the extrinsic membrane proteins are associated with these proteins, or the head groups of the bilayer lipids. The salient amphiphaticity makes it difficult to detach integral proteins from the lipid membrane, and the use of detergents is necessary in order to solubilize the membrane and get the proteins into solution. The difficulty of finding appropriate conditions increases with the number of components in the system, and a series of different steps are often needed in order to prepare injectable samples of the different proteinaceous components of membranes. Strategies for finding these conditions, as well as choosing separation technique and detergents, are outlined by Josic et al.\(^{769,770}\) Tools for predicting transmembrane regions in a protein are available through the ExPaSy server\(^{576}\) and might be useful in method development.

Once the proteins have been solubilized, they are amenable to separation by practically the entire array of separation chemistries applicable to proteins. There are some particular problems that should be kept in mind, such as microheterogeneity due to differences in glycosylation pattern, irreversible adsorption to the column due to nonspecific interaction, the tendencies to precipitate or aggregate, and the strain put on the system because of the high concentrations of salt, detergents, or other denaturing reagents that may have to be added to the eluents to overcome these tendencies. Subject to the nature of the protein, mild detergents can be sufficient to suppress aggregation and precipitation, in which case separation can be made under nondenaturing conditions with IEC, hydroxyapatite, HIC, and various affinity chemistries. Otherwise, or if the selected separation chemistries are SEC and RPHPLC, the addition of strong, denaturing detergents, urea, or other denaturing agents is normally necessary. Solubilizing detergents also tend to dynamically modify the stationary phase by adsorption, leading to substantial changes in interaction patterns.\(^{769}\) Lundahl et al.\(^{771}\) evaluated hydroxyapatite columns of different brands for separation of integral membrane proteins solubilized in SDS (sodium dodecyl sulfate) and found considerable differences in elution pattern (Figure 57).

von Jagow and Schgger have presented a monograph devoted entirely to practical aspects of membrane protein purification.\(^{764}\) An interesting ancillary development that should be mentioned in connection with membrane proteins is the use of immobilized liposomes, proteoliposomes, or biomembranes for studies of interactions of proteins with lipid surfaces.\(^{6,414}\)

8.3.2 Lipoproteins

Serum LPs are complexes between proteins and lipids found in blood serum. The core consists of hydrophobic components such as triglycerides or cholesterol esters, shielded by an amphiphilic layer that is comprised mainly of proteins (Figure 58).

![Figure 57](image1)

**Figure 57** Chromatograms of solubilized human erythrocyte integral (intrinsic) membrane proteins in complex with SDS using hydroxyapatite HPLC columns of four different manufacturers: (A) Tonen Taps-020810, (B) PENTAX SH-0710F, (C) A-7610 and (D) TSKgel HA-1000. The SDS–polypeptide complexes (0.5 mg) were eluted with a phosphate buffer concentration gradient at a flow rate of 0.8 mL min\(^{-1}\). The height of each panel corresponds to 0.12 absorbance units at 280 nm. Arrows indicate fractions that were analyzed by electrophoresis. Conductivities of 10, 20 and 30 mS cm\(^{-1}\) at 25 °C correspond to phosphate concentrations in the eluent of 85, 205, and 370 mM, respectively. (Reproduced from P. Lundahl et al., *J. Chromatogr.*, 604, 98 (1992) by permission of Elsevier Science B.V.)

![Figure 58](image2)

**Figure 58** Diagram of an LP particle. (Reproduced from T. Takey, W.C. Purdy, *J. Chromatogr. B*, 671, 238 (1995) by permission of Elsevier Science B.V.)
LPs are classified as high-density lipoproteins (HDLs), low-density lipoproteins (LDLs), and very-low-density lipoproteins (VLDLs), determined by the relative buoyancy in a tedious, complicated, and time-consuming gradient ultracentrifugation process. Takey and Purdy(772) reviewed preparative and analytical separations of LPs, using SEC, affinity chromatography, and HPLC techniques for resolution of structurally different LPs. A review of separation strategies for LPs was also recently presented by Shibusawa,(611) who concluded that the preferred separation technique for HPLC of LPs is hydroxyapatite chromatography with step changes in phosphate concentration at pH 7.4 for elution (Figure 59). This technique can separate all three classes of LPs, but is unable to resolve HDLs from serum albumin and globulin. A complementary technique is CCC, which offers the very mild separation conditions required to preserve the structures of the aggregates during separation. Combined use of these two techniques with CCC as a preliminary fractionation step for final separation by hydroxyapatite chromatography is capable of resolving all three classes of LP.(611) Note that CCC is not an HPLC technique, and it requires highly specialized and quite complicated equipment.

8.3.3 Recombinant Proteins

Proteins expressed in prokaryotic organisms impose particular challenges on chromatographic separations for purification and analytical purposes. Glycosidation patterns of recombinant proteins are often different from proteins expressed in eukaryotic systems, protein folding is an issue, and the extraction of proteins that are excreted by eukaryotic cells but remain inside prokaryote organisms may call for rigorous conditions for solubilization or separation(773,774) of inclusion bodies. The use of column chromatography for the purification of recombinant proteins was reviewed by Jungbauer and Boschetti(775) with special emphasis on validation and on long-term stability in the chromatographic separation processes. Evangelista Dyr and Sutttnar(758) reviewed methodologies applicable to the purification of recombinant proteins, including sample preparation and assays methods, and compared the techniques with those used in the purification of conventional proteins.

A correct disulfide bonding pattern is central for folding of recombinant proteins and verification of correct disulfide linkages should therefore be part of the quality control scheme for recombinant proteins. Lei et al.(776) described the use of tryptic mapping of recombinant human growth hormone on an immobilized enzyme cartridge, followed by on-line separation of fragments by TFA/acetonitrile RPHPLC (Figure 60). The MALDI/TOFMS technique was used to verify the absence of peptides with mismatched disulfide bridges. Ikegaya et al.(777) used the Edman degradation and pepsin mapping followed by HPLC on C18 columns to elucidate the exact positions of the disulfide bridges in a purified recombinant HSA. General characterization of recombinant proteins is often performed with CE instead of by HPLC.(778,779)

8.3.4 Enzymes

In analytical separations of biomolecules, it is often sufficient to establish stable and reproducible conditions so that the molecule under study elutes as a single well-shaped peak at a predictable retention time, separated from other macromolecular components of the sample. Denaturation and loss of biological activity that accompanies conformation changes is therefore often an intentional part of the sample preparation. It may also be induced by the choice of mobile phase components or stationary phases that lead to controlled denaturation. Enzymes are different, because the purpose of a separation is typically to recover the enzyme in its native state with maintained biological activity, in particular in preparative high-performance separations. The in vitro stability of enzymes varies, with some being quite unstable. Special techniques are therefore often required when the goal of the separation is to preserve biological activity, a topic addressed in a review by Kaufmann.(86) Among the techniques advocated are perfusion chromatography and the use of tentacle gels(165) to accomplish fast chromatography on soft interaction media.

Toribio et al.(780) have reviewed recently developed protocols for the purification of pyridine nucleotide-dependent enzymes. All of the referred protocols made use of chromatographic steps, with affinity
purification techniques for glutathione-related enzymes. Toribio et al. have also reviewed stationary phases specific for individual enzymes as a goal for the future. The need to utilize more than one separation dimension in an overall purification scheme was obvious – two or more chromatographic techniques with different selectivities were used in more than 90% of the protocols, and in more than half of the protocols three or more chromatographic dimensions were used.

The purification of carbonic anhydrase isozymes from different sources was reviewed by Bergenhem, with emphasis on application of their sulfonamide complexes in single-step affinity schemes. Kopperschlager and Kirchberger reviewed methods for the separation of LDH and its isoforms, concentrating on affinity separation techniques using natural and pseudo-biospecific ligands. Methods for the separation of superoxide dismutase isoenzymes were reviewed by Michalski along with techniques for monitoring their purification and measuring their activity. Lin et al. provided an overview of methods for the purification of hydroxysteroid dehydrogenases, mainly by HIC and dye-affinity chromatography. Sample preparation, prefractionation, and separation techniques for mamalian cytochrome enzymes based on IEC, hydroxyapatite, HIC, and immobilized metal affinity systems were reviewed by Roos. Multistep separations using SEC, IEC, hydroxyapatite chromatography, and RPHPLC for the isolation and characterization of mammalian catechol-O-methyltransferase were reviewed by Tilgmann and Ulmanen. A wide array of chromatographic techniques (RPHPLC, IEC, HIC, TAC, and affinity schemes based on sorbents with phenylboronate, immobilized metal ions, and cyclodextrin and starch as biospecific ligands) applicable to the separation of α- and β-amylases and their isoenzymes from complex extracts was reviewed by Brena et al. Moriyama and Ikeda reviewed the assay of clinically relevant amylase enzymes, acting on glycosidic bonds.

The purification of proteases using HIC and affinity schemes with cyclic peptide antibiotics and immobilized dyestuffs as protease-specific ligands was reviewed by Ibrahim-Granet and Bertrand. Hamada reviewed the use of preparative HPLC for the large-scale production of carbohydrate hydrolases, proteases, and transglutaminases from food, microbial and plant sources for industrial applications. Parmentier et al. reviewed the purification of glutathione synthetase, glutathione reductase, γ-glutamylcysteine synthetase, and γ-glutamyltranspeptidase by the use of multiple LC separations. Isolation of transglutaminase isofoms from tissue and body fluids along with procedures for purification of γ-glutamyltransferases were reviewed by Wilhelm.
et al.,(791) particularly addressing the problems caused by formation of irreversible aggregates. The most widely used separation techniques were SEC and IEC. Affinity schemes based on heparin for the purification of lipases, phospholipases, and kinases were reviewed by Farooqui et al.(448) Focus was also placed on techniques for attaching heparin to supports and detecting its presence after immobilization. Raspi(792) presented a review of sample preparation, purification, and assays for isolating and determining kallikrein proteinases from tissues and body fluids. Knudsen et al.(793) reviewed chromatographic and electrophoretic separation strategies for eukaryotic DNA topoisomerases isoforms, and the techniques used for determining their catalytic activity. The added benefit of high-sensitivity metal analysis by coupling a separation of metal-containing enzymes to inductively coupled plasma mass spectrometry (ICPMS)(794) is illustrated in Figure 62.

The availability of assay techniques is central for determining the biological activity of enzymes during and after isolation. Many such assays are based on HPLC, and a few overviews covering different HPLC assays have appeared in the recent literature.(754,795–797)

8.3.5 Protein Folding and Unfolding Studies using High-performance Liquid Chromatography

By virtue of the large variations in surface properties and the possibility of controlling the interaction time and strength by manipulating the eluent parameters, liquid chromatographic techniques lend themselves to studies of protein folding and unfolding, the processes responsible for denaturation and irreversible adsorption of proteins on sorbent interfaces. Modulation of the hydrophobicity of polymethacrylate coatings on porous and nonporous silica enabled Hanson et al.(142) to mediate selective unfolding of proteins on the sorbent surface, conformational changes that made it possible to alter the separation pattern of the protein probes lysozyme, cytochrome c, and myoglobin. Similar effects were seen for synthetic peptides with defined secondary, tertiary, and quaternary structures.(143) Benedek(798) studied the unfolding

---

Figure 61  General purification scheme suitable for NADP<sup>+</sup>-dependent enzymes according to Toribio et al.(790) (Reproduced from J. Chromatogr. B, 684, 2 (1996) by permission of Elsevier Science B.V.)
of recombinant human brain-derived neurotrophic factor on butyl columns by varying the temperature and incubation time in acidic RP eluents, and found that the data supported a process wherein the dimeric protein is first attached to the surface, then dissociated into its monomeric units, which are subsequently unfolded. The unfolding mechanisms were different in acetonitrile and 1-propanol eluents. Purcell et al.\(^{599}\) used peptides as probes with butyl and octadecyl RP stationary phases over a wide range of temperatures, and found that the bandwidth could be correlated with secondary structure and dynamics of conformational changes. Richards et al.\(^{277}\) studied the retention behavior and conformational states of cytochrome c of different origin in RPHPLC on C\(_4\) and C\(_{18}\) columns by using aqueous TFA/acetonitrile eluents at different gradient times and elution temperatures. In a simultaneously published work, the same group\(^{800}\) made use of variations in the \(4\sigma\) bandwidths of the eluted peaks to study how the secondary and tertiary structures contributed to the interaction of these proteins with the stationary phases.

Hodges et al.\(^{801}\) correlated the retention differences of two synthetic amphiphatic \(\alpha\)-helical peptides differing in three residues (valine and isovaline, respectively) and on a C\(_8\) column with CD measurements of their helical stability. A study on how the recoveries of albumin, fibrinogen, and IgG varied with the time the proteins were allowed to be in contact with nonporous strong anion and cation-exchange materials was done by Goheen and Hilsenbeck.\(^{570}\) by adjusting the salt gradient steepness. They found that recoveries were correlated to the residence times and ascribed their results to an initial weak binding followed by a stronger attachment, whose time dependence is due to the time required by the protein to unfold on the charged surface (Figure 63). Related to the area of protein folding is also the studies of chaperonins, proteins that assist in or accelerate protein folding and prevent aggregation, the purification of which was recently reviewed by Quaitte-Randall and Joachimiak.\(^{802}\)

### 8.4 Carbohydrates and their Conjugates

Polysaccharides play very important and highly diverse roles in biological systems, ranging from basic energy...
storage, over structurally reinforcing and impact-damping elements, to complex signaling and recognition systems. Furthermore, biologically derived carbohydrate macromolecules have a large economic importance in industry, as rheological modifiers in the food and cosmetic sectors, and as a basis for the paper pulping and the vegetal fiber textile industries. Process and quality control in these industries calls for ways of isolating and characterizing polysaccharides, which are often of very high molecular weight, with respect to differences in composition, branching, and charge. Polynucleotides are, although treated separately here, in principle also carbohydrate polymers, although their pendant nucleotide bases provide other possibilities for separation. In other areas of the bioscience, substantial interest is presently devoted to glycoconjugates of polypeptides and lipids. Their characterization requires techniques for separating relatively small polysaccharides cleaved from the conjugates, and also of smaller oligosaccharide fragments and single monosaccharides after enzymatic cleavage. The differences sought in these compounds are often subtle and highly demanding on the separation chemistry. Techniques used for studies of carbohydrates are consequently highly diverse.

The basic property of polymeric carbohydrates is their monomeric structure, i.e. the kind and sequence of sugars incorporated. Branching is also central, as is charge derived from the presence of carboxylic groups, sulfate moieties, or amino groups on the sugars. When the polysaccharide reaches a certain length, these properties will have a large impact on its behavior and also its HPLC separability. Very large polysaccharides are almost exclusively separated by HPSEC, and the first problem facing the analyst is to ascertain that the sample is properly dissolved, and that the association between chains is minimal in the separation solvent. Most large polysaccharides will dissolve in water and can be separated in aqueous eluents, although both the dissolution and separation will often require heating to overcome associations that manifest in gelation behavior. Although silica can be used for the separation of many carbohydrates, it will not withstand elevated temperatures over a long time. Polymeric stationary phases are therefore preferred. Solute dissolution usually takes place quite readily when the polysaccharides are charged or highly branched, whereas uncharged polysaccharides with little or no branching form crystalline structures that require more vigorous conditions for dissolving and keeping the polymers from aggregating in solution. For example, cellulose and chitin take several days to dissolve by swelling in \( N,N \)-dimethylacetamide/LiCl. This is the only solvent system known to dissolve underivatized cellulose, and is also used in the HPSEC separation\(^{803}\) (Figure 64).

Another problem in SEC of high-\( M_W \) charged polysaccharides is their high intrinsic viscosity, caused by their expanded configuration in solution. Macromolecular crowding will occur if the injected concentrations are too high in a SEC separation, due to entanglement of the polymers chains approaching the pore system. This solute-induced restricted access to the pore space produces peak distortions, which effectively maximizes the sample concentration. For very high molecular weights the maximum acceptable concentration can be as low as 0.02\%. With injected concentrations this low detection becomes difficult, augmented by the absence of natural chromophores in polysaccharides. Introduction of a detectable group, such as a fluorescent group, onto high-molecular-weight polysaccharides by derivatization has yielded only limited success, because the labeling becomes less efficient as the molecular size increases.\(^{805}\) Molecular weight calibration of polysaccharides in SEC is furthermore a source of concern. The shape factors of polysaccharides vary quite strongly, so different polysaccharide molecular weight standards are not directly interchangeable. Pullulans and dextrans can be acceptable as calibration standards for compounds with similar solution behavior, but a better alternative to external calibration is to use a MALLS detector (see above), or a combination of some other scattering and viscosity measurements, to determine the molecular weight on-line. Carbohydrate separation by SEC, including considerations for selection of columns, has been reviewed by Churms.\(^{806}\)

More separation options are available for oligosaccharides and smaller polysaccharides. Although sugars are very polar, RPHPLC of uncharged oligosaccharides is possible on regular alkylsilane columns. However, the retention for underivatized oligosaccharides is so low that almost totally aqueous eluents have to be used,
conditions that are known to result in phase collapse and eventual expulsion of eluent from the pore system. The bonded phase density also has a profound effect on retention, as does the presence of uncapped silanol groups. Dissociation of carboxylic carbohydrates such as pectin and its fragments can be suppressed by the use of acidic eluents. The retention for acidic carbohydrates can be increased by formation of ion pairs with cationic tetraalkylammonium ions, in a process that can be regarded either as the result of partitioning of hydrophobic ion pairs formed in the liquid phase, or a dynamic coating of hydrophobic cations onto the RP sorbent, effectively transferring it into a cation-exchange sorbent. Porous graphitized carbon (PGC) offers separation according to the RP principle. The retention is higher compared to alkylsilane columns and the PGC columns have a more pronounced selectivity, which appears to be substantially influenced by the solute shape. The resolution of anomeric forms and closely related oligosaccharides is therefore possible, as illustrated in Figure 65.

Of opposed selectivity to RPHPLC is HILIC, practiced on polar stationary phases with aqueous eluents containing relatively high concentrations organic solvent, typically acetonitrile. A wide variety of stationary phases have been used for HILIC separation of diverse carbohydrates, ranging from monosaccharides to relatively large sialic and asialic oligosaccharides. The retention shows a marked influence on the nature and position of sugar units, and HILIC is therefore valuable in separations of hetero-oligosaccharides, exemplified by an ability to separate recombinant human interferon-γ based on site-specific glycosylation microheterogeneity (Figure 66). The use of HILIC for separation of carbohydrates has been reviewed.

Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates. Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates. Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates. Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates. Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates.
The anionic properties of sialic carbohydrates provide for direct separation, but neutral carbohydrates need to be complexed by borate to form anionic species that are retained on anion-exchange resins. This technique is now largely obsoleted by high-pH anion-exchange chromatography (HPAEC) using strongly alkaline eluents to promote a dissociation of the carbohydrate hydroxyls, so that neutral sugars are converted into anionic species. Thus, HPAEC is applicable to both sialic and asialic oligosaccharides without the need to add a separate complexing agent. Hydroxide ion is a weak eluent, so solutes are eluted from the column by an increasing concentration of a pushing ion, typically acetate or nitrate (Figure 67). The retention is largely a function of the number of hydroxyl groups, corresponding to the degree of polymerization. Obviously, high-pH eluents necessitate the use of hydrolysis-stable polymeric columns. An advantage of the alkaline eluent is that the separated sample can be detected by a PAD detector (see above) without postcolumn addition of base. The disadvantages of high-pH eluents are epimerization and degradation of the samples, to which there is no good solution. Still, HPAEC has secured a central position among modern HPLC techniques for oligosaccharide separation. Sialylated oligosaccharides can be separated from asialics by elution at a lower pH, although base must then be added to enable detection by PAD. The HPAEC technique has been reviewed by Lee. Affinity chromatography of carbohydrates is possible either through the formation of cyclic boronate esters with aminophenylboronic affinity phases, which is a technique particularly valuable for sample work-up and enrichment, or by the use of immobilized lectins (see affinity section). Glycoaffinity chromatography and its applications in studies of biological recognition has been reviewed by Caron et al.

Absence of detectable groups is a concern not only for high-molecular-weight carbohydrates, as outlined above. Saturated carbohydrates absorb light only at very low UV wavelengths, where the chemical noise from other sample compounds and solvent contamination becomes problematic. Monounsaturated sugars produced by enzymatic cleavage have their absorption wavelength somewhat shifted, but still in the low UV. Derivatization reactions aimed at enhancing the detectability of oligosaccharides have therefore been employed for many years. Derivatization could aim at any of the polar groups in polysaccharides, but this is not practical for several reasons, except in GC and SEC where the purpose is to reduce the polarity of sugars and oligosaccharides.

![Figure 67](image)

**Figure 67** Separation of Neu5Ac oligo/polymers derived from colominic acid (equivalent to 100 µg) on a CarboPac PA-100 column using an eluent containing 0.1 M NaOH with a superimposed 1 M NaNO₃ (E1) gradient, as indicated in the figure. Detection was by pulsed amperometry, using a gold working electrode. The inset shows an enlarged view of the retention time interval between 61 and 74 min. Peaks are labeled with degree of polymerization. (Reproduced from Y. Zhang et al., *Anal. Biochem.*, 250, 247 (1997) by permission of Academic Press.)
Instead the reducing end of the polysaccharide is targeted, which is also used to deal with a separation problem in interactive chromatography of small sugars, namely the splitting of α- and β-anomers and their on-column isomerization leading to badly shaped double peaks. This can be eliminated by derivatization schemes using reductive amination (see Figure 68).

Introduction of a nonpolar group in the terminal end of the oligosaccharide also has a positive effect by increasing the interaction with RP sorbents. Postcolumn derivatization as a means of modifying carbohydrates for spectrophotometric, fluorimetric, or electrochemical detection in HPLC has been reviewed by Honda.

In glycosylated proteins, the borderline between a protein and a polysaccharide is diffuse, indicated by their nomenclature. Glycoproteins comprise anywhere from 1% to 80% of their weight as oligo- and polysaccharides attached to their surfaces, which should intuitively lead to a substantial change in their interaction patterns. The influence of this carbohydrate modification is surprisingly low, however, and glycoproteins are therefore isolated on the basis of their protein properties (charge and hydrophobicity), rather than on the basis of their carbohydrate properties. Affinity chromatographic schemes, hydroxyapatite chromatography (Figure 69), or CE are useful when glycosylation pattern heterogeneities are sought. The use of HPAEC for separation of glycopeptides obtained in tryptic maps was recently reviewed by Townsend et al. Proteoglycans, which have a protein core—usually a glycoprotein—may contain up to 95% oligo- and polysaccharides of 200 or more disaccharide units, and reach molecular weights in excess of 1 MDa. Their extraction from tissue requires special consideration and separation is mostly carried out on SEC or non-HPLC techniques. Proteoglycans—sometimes called proteoglycan chains of proteoglycans—are composed of alternating uronic acid and N-acetylgalactosamine residues, which give the molecules a net negative charge, augmented by sulfate groups attached to hydroxyls. According to Alberts et al., these oligosaccharides have an almost limitless heterogeneity potential, which obviously makes chromatographic separations and other means of characterization difficult. The complicated biochemical pathways involved in the biosynthesis of oligo- and polysaccharides attached to lipids and proteins are indicators of their important function, but most of these biological functions are still not known. Glycobiology is consequently an important and growing area in molecular biology, dealing with elucidation of the cellular functions of glycoconjugates. The first steps in this work is to characterize the carbohydrate moieties. Although modern MS techniques have evolved into extremely powerful tools for glycobiology, the complexity of carbohydrates and their conjugates still calls for a battery of separation and detection steps coupled with chemical and biological modifications to accomplish the most complicated characterizations. The use of CZE and supercritical fluid chromatography has been reviewed and is not covered here.

Characterization of oligosaccharides conjugated to other biomolecules requires that they are detached from their protein, peptide, or lipid components, a feat nowadays accomplished by enzymes. Prior to cleaving the carbohydrate portion from glycoproteins, these are usually broken down into peptides by proteases, so that steric hindrance in the enzymatic detachment is minimized. Detachment of N-linked oligosaccharides is feasible by several enzymes, either at the TOC.

**Figure 68** Normal-phase HILIC chromatography of oligosaccharides in human milk derivatized by reductive amination with 2-aminoacridone on a GlycoSep N column (250 × 3.9 mm i.d.): (a) blood group O, (b) blood group A, and (c) blood group B. Mobile phases: A, acetonitrile; B, 250 mM ammonium formate, pH 4.4. Gradient: 20–58% B over 152 min. Fluorescence detection at 428/525 nm. (Reproduced from J. Charlwood et al., *Anal. Biochem.*, 273, 275 (1999) by permission of Academic Press.)
Asn linkage by glycosamidase resulting in an intact oligosaccharide, or by an endoglycosidase leading to an oligosaccharide deprived of the N-acetylglycosamine linkage. No well-characterized enzyme systems are available today that are capable of general release of O-linked oligosaccharides. Released fragments are usually subjected to further enzymatic cleavage by exo- or endoglycosidases of high specificity, targeting particular glycosidic linkage patterns in the oligosaccharide, whereafter the fragments are separated and identified. Large amounts of structural information can be produced in a short time if arrays of enzymes are used. The most recent developments in this area dispose of the chromatographic separation step entirely and carry out the enzymatic reactions directly on a MALDI target. Yet modern biomacromolecule chromatography is indispensable in glycobiology, because the purity of the enzymes used is obviously of paramount importance to the reliability of the data produced.

A combination of separation techniques into multidimensional separation schemes is required to elucidate the complicated structures of oligosaccharides in biological systems, and even three-dimensional separation maps with orthogonal selectivities have been described. Several books on carbohydrate analysis have also been published during the 1990s.

8.5 Validation of Separation Processes

From the preceding text, it is obvious that HPLC is becoming a viable alternative to many conventional techniques for preparative purification of proteins and other biotechnologically derived products, due to the high speed and separation potential. Whenever a chromatographic technique is adopted as part of a production scheme for a therapeutic formulation, stringent rules apply to the validation of the separation method. Aspects such as assessing the long-term consistency of retention, the possibility of cleaning and sterilizing separation columns in-place and the possible deterioration of phases due to such actions leading to release of leachable compounds are treated in a recent review by Jungbauer and Broschetti.

9 TRENDS IN SEPARATION MEDIA FOR HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY OF BIOMACROMOLECULES

During the 1990s, there has been a tremendous development in new separation media for biological macromolecules, in particular proteins. Low diffusion coefficients are the Achilles’ heel of large-molecule chromatography, leading to a steep decrease in efficiency resulting from the contribution to factor C (Equation 15) of the van Deemter–Knox equation (Equation 12). The activities aimed at improving the separation efficiency have therefore focused on the physical configurations of sorbents to enhance the mass transfer. Much less has been done in the area of chemistries of the separation media.
Efforts to improve mass transfer can be divided into three major areas:

- Decreasing the particle size to diminish the intraparticle diffusion length.
- Avoiding the intraparticle diffusion using active sites on nonporous supports (micropellicular materials).
- Facilitation of the intraparticle mass transfer by convection (Figure 70).

### 9.1 Nonporous and Micropellicular Separation Media

Supports may be classified according to the spatial distribution of pores as nonporous, superficially porous, and totally porous. Micrometer-sized nonporous silica particles were introduced in the 1980s as a means of alleviating the problem of mass transfer limitations that results from the slow intraparticle diffusion. Although the advantage of elimination of intraparticle diffusion could be demonstrated, these nonporous particles have an extremely low surface area compared to porous media. As the separation proceeds mainly at the surface, both very low sample capacity and retention are typical for these packings. Based on a solid SiO$_2$ density of 2.2 g cm$^{-3}$, the surface area of a packed bed of 5 µm spherical particles is as low as 0.6 m$^2$ mL$^{-1}$, and even if the particle size is decreased to 1 µm, the surface area is increased to only 3 m$^2$ mL$^{-1}$. This is about two orders of magnitude lower than the typical porous silicas useful for the separation of biological macromolecules. A comparison of porous and nonporous microparticulate RP silicas used in the separation of two closely related peptides also shows that the pellicular material is more sensitive to changes in the mobile phase due to the overall low coverage with interaction groups.

![Figure 70](image)

**Figure 70** Overview of the routes taken to improve the separation efficiency for biological macromolecules by reducing the mass transfer resistance in the partitioning process. (Reproduced from A.E. Rodrigues, *J. Chromatogr. B*, 699, 48 (1997) by permission of Elsevier Science B.V.)

Fast separation implies that denaturation can be kept at a minimum. Protein separations can be carried out at elevated temperatures, and all columns appeared to have essentially the same efficiencies, due to the binary sorption conditions during the steep gradients (Figures 71 and 72).

There are still substantial advantages inherent in the use of nonporous media. Solid particles are extremely hard and can tolerate very high differential pressure across the packed beds. The nonporous surface with a well-defined topography enables high accessibility of the interaction layer and the absence of pores ensures that separations are not affected by exclusion processes. In specific applications, the low retention can be used to an advantage, as it makes the use of mild eluents mandatory. In combination with a low column void volume, and the inherent high efficiency, columns packed with nonporous particles provide for very fast separations. This appears to be the principal advantage of nonporous microparticles. Fast separation implies that denaturation can be kept at a minimum. Protein separations can be carried out at elevated temperatures.
to further enhance the separation. The decreased eluent viscosity promotes both diffusion and interaction kinetics and lowers the back-pressure. An example of a rapid separation under these conditions is shown in Figure 73. It should be noted that this separation is carried out under conditions that are denaturing the analytes even at normal temperature. Thus, the use of high temperature does not alter the situation. However, denaturing does not appear to be a major issue in analytical separation unless the purpose of the separation is elucidation of tertiary or higher protein structure, and can therefore be acceptable as long as the peaks are eluted singly in narrow bands at predictable retention times, and provided that the stationary phases are not irreversibly damaged by precipitated protein.

Figure 72 Fast protein separations on bonded C<sub>18</sub> nonporous silica with particle diameter (a) 2 µm (b) 5 µm, and (c) 20 µm at 4 mL min<sup>-1</sup> flow rate and 75°C. Linear gradient from 22% to 100% eluent B (Figure 71) in 48 s. Peak identities: 1, insulin B chain; 2, insulin; 3, lysozyme; 4, α-lactalbumin; 5, carbonic anhydrase. Figures 71 and 72. (Reproduced from N. Nimura et al., *J. Chromatogr.*, 585, 209 (1991) by permission of Elsevier Science B.V.)

Obviously, separations on nonporous packings are limited to analytical and micropreparative scale because of the low loading capacity. Another consequence of the low capacity is the need for sensitive detection. Although this is partly compensated for by the high concentration of the analyte in narrow peaks, separations in columns packed with nonporous materials require more sensitive detection techniques.

The development of current micropellicular separation media represents a revival of technology of the early days of HPLC. Many pellicular sorbents of that time were provided with thicker interaction layers compared to the current monolayer functionalized silicas. Today, the term micropellicular separation media is used to describe all smooth, nonporous particles that are monolayer functionalized, or covered with polymer shrinkwraps, superficially porous layers, polymer tentacles, and electrostatically attached layers of polymeric latex particles. Pellicular layers can also have a polymeric core and an inorganic interaction layer. Monolayers have little effect on increase of the loading capacity and merely serve the purpose of outfitting the surface area with a suitable interaction layer. This is similar to the processes used for functionalization of internal surfaces of porous beads. The same applies...
to smooth and dense polymer shrink-wraps regardless of their thickness, as biomolecules typically interact only with the surface. However, the difference in loading capacity compared to a porous sorbent is lower than may be expected, because the interior surface of a porous material would be largely inaccessible to a slowly diffusing protein at the separation speeds used with nonporous microparticles,\(^\text{100}\) evident also in Figure 71. A majority of the polymer coating techniques described earlier in the text have been used for coating smooth microparticles.

Most separation chemistries have been implemented on micropellicular media except, for obvious reasons, SEC. Unger showed that RP separation of proteins and peptides can be done with high efficiency on C\(_18\), C\(_6\), C\(_4\), C\(_2\), and phenyl-modified monodisperse 1.5-\(\mu\)m nonporous silica,\(^\text{838}\) and that hydrophobic interaction chromatographic interaction layers can be established on these supports activated by diethylene glycol allyl methyl ether and acetamidopropyltriehtoxysilane.\(^\text{841}\) The recovery of proteins (pepsin, catalase, and horseradish peroxidase) in their native state on the RP materials showed the expected dependence on ligand chain length, solvent admixture, and contact time.\(^\text{842}\) Coating with PBD was later shown to be a useful alternative for providing a hydrophobic coating on nonporous silica.\(^\text{135}\)

Examples of affinity chromatographic separations are glycoproteins and Igs on columns with immobilized protein A, concanavalin A, or wheat-germ agglutinin,\(^\text{100}\) and the separation of cytochrome c, lysozyme, and chymotrypsinogen A by rapid metal-interaction chromatography on IDA ligands charged with Co\(_{2+}\), Fe\(_3+\) or Ni\(_{2+}\) ions.\(^\text{843}\) Preparation of micropellicular silica phases with RP, anion exchange, and hydrophobic interaction surface layers and their use for rapid separation of proteins was demonstrated by Kalghatgi.\(^\text{844}\) A micropellicular sorbent for HILIC based on aminofunctionalized nonporous silica was recently used by Lin and Lee for separation of a fructo–oligosaccharide mixture.\(^\text{213}\)

Micropellicular sorbents prepared from 3-\(\mu\)m cross-linked polystyrene beads were used for separation of proteins in RP mode at different pH and temperature by Maa and Horváth.\(^\text{845}\) Although some swelling was observed in organic solvents, typical RP eluents did not have any negative effect on the efficiency, which was found to be best at the extreme ends of the tested pH scale. Polystyrene beads were also functionalized with DEAE groups and used in anion-exchange mode for fast separation of DNA fragments with gradients of aqueous buffers as eluents.\(^\text{846}\) Letourneur et al.\(^\text{847}\) converted nonporous polystyrene into phosphate-type ion exchangers. The pellicular separation media most widely used are the ion exchange resins with agglomerated latex coating first described by Small et al.\(^\text{840}\) for the separation of small ions by IEC. Modern tentacle-type sorbents with application areas directed towards separations of macromolecules\(^\text{575}\) originated from this work.

A different type of nonporous medium, deswollen and cross-linked agarose beads, was described by Hjerten and Liao.\(^\text{848,849}\) These particles are prepared by suspending macroporous agarose beads in a solvent mixture that contains dioxane and chloroform, followed by cross-linking of the shrunken beads with 1,4-butenediol diglycidyl ether. This treatment leads to particles with diameters as small as 3\(\mu\)m, with sufficient mechanical stability to be packed and used for separation. However, the cross-linking renders the agarose more hydrophobic and makes it suitable for HIC.\(^\text{848}\) Treatment with glycidol enhances the hydrophilicity of the surface. Functionalization to an anion exchanger and its use in IEC of a number of proteins was also demonstrated\(^\text{849}\) (Figure 74). Yet another variety of nonporous support are 0.5-\(\mu\)m quartz fibers, which were silylated with mercaptopropyltrimethoxysilane and coupled with treysyl chloride-activated dextran by Wikström and Larsson to afford affinity supports. After derivatization with a NAD (nicotinamide adenine dinucleotide) ligand, this medium was used for rapid processing of enzymes from dilute solutions.\(^\text{310}\)

![Figure 74](image_url) Separation of proteins on a compressed, nonporous anion exchange column (62 x 6mm i.d.; 15\(\mu\)m) prepared by reacting with dimethylamine a macroporous agarose that had been rendered nonporous, cross-linked, and activated by 1,4-butenediol diglycidylether in solvent. Linear gradient over 2.5 min from (A) 10mM TRIS-HCl, pH 8.5, to (B) 180mM sodium acetate in (A), at a flow rate of 4mL/min. Chromatogr., 457, 180 (1988) by permission of Elsevier Science B.V.)
Two reviews have been published on the use of nonporous stationary phases in biomacromolecule separations. Lee et al. focuses on the preparation and functionalization of nonporous sorbents and the dynamics of protein separation and offers a comprehensive listing of commercially available nonporous sorbents; the topic of Huber is separation of double-stranded DNA on micropellicular stationary phases by anion-exchange or ion pair chromatography. Chen and Horváth placed micropellicular sorbents in a wider perspective of HPLC development in their review of high-speed HPLC of peptides and proteins.

9.2 Perfusion-type Particles with Large Open or Gel-filled Pores

As outlined in the introductory part of this article, the main obstacle against high efficiency separations, with a sample capacity sufficient for preparative applications on conventional porous sorbents, is the intraparticle mass transfer resistance, i.e. the pools of stagnant mobile phase that the solutes have to move across in order to interact with the internal pore surfaces. One way of enhancing the mass transport in porous media, through augmented diffusivity by convection, was described in the chemical engineering literature in the early 1980s. After the concept was applied to protein separation media in the late 1980s, the technique became known as perfusion chromatography. The underlying principle is quite straightforward. By ascertaining that the sorbent has a sufficiently large pore size, the differential pressure across the particle forces part of the eluent through the sorbent particle, in addition to the flow around it through the interstitial voids. This convective transparticle flow enhances the mass transfer through the macroporous space within the beads, so that the solutes are brought more quickly into contact with the interacting sites. A transparticle flow of only a few percent of the total flow is sufficient to increase the efficiency substantially. Characteristic of convective transport is that the factor $C$ in the van Deemter–Knox equation levels off at a critical flow rate, and that the efficiency beyond that point becomes nearly independent of the eluent flow velocity. In other words, the column throughput per unit time increases almost linearly with eluent flow rate, without a band-broadening penalty. Another beneficial effect of the more efficient mass transport in the convective regime is that, unlike conventional porous sorbents, the useful dynamic capacity of the sorbent is preserved at high flow rates. The theory of convection-enhanced internal mass transport in particles has been worked out by Rodrigues et al., Liapis et al., and by Carta et al. For example, the extended version of the van Deemter–Knox equation (the Rodrigues equation) adequately describes the mass transfer enhancement for biomacromolecules in perfusive sorbents (Figure 75).

Perfusive sorbents are typically used as relatively large particles (10–40 µm) in small to medium scale preparative separations. They can therefore be operated in the augmented transport regime at high linear flow rates without excessive back-pressure. The most valuable feature of perfusion chromatography is the speed of separation, which allows high throughput processing using relatively small columns operated in automated systems.

There are currently two different types of augmented diffusivity materials on the market, contrasting with respect to the medium occupying the pore system. The material first introduced is a megaporous styrene–divinylbenzene sorbent with a bimodal pore size distribution. These sorbents contain very wide pores with a diameter of 600–800 nm transecting clusters of spheroid microglobules containing 50–150 nm small diffusion pores that also account for the majority of the interaction surface area. Another material, introduced a few years later, is a soft-gel-in-a-rigid-shell aerogel–xerogel composite, comprising a rigid hyperporous polystyrene–silica composite that has the pore space filled with a lightly cross-linked soft hydrogel, which is also the carrier of the interactive groups. The presence of a hydrogel inside the pore system increases the capacity and lowers the eluent flow rate where the transition from the diffusive to the convective operation takes place, so that the efficiency is independent of flow rate in practically the entire operational range.

Superporous agarose, prepared by Gustavsson and Larsson using the double emulsifier technique, has also the attributes of a perfusion sorbent, although the size of both particles (300–500 µm) and the through pores
(25–75 µm) are considerably larger than those of the rigid synthetic porous polymers discussed above. For this reason it hardly qualifies as an HPLC sorbent. In fact, the intraparticle superpores are so large that the convective flow can be monitored by videomicroscopy of dyed microparticles moving through the pores. The advantages of intraparticle flow within these beads have been demonstrated in ion-exchange, hydrophobic interaction, and affinity chromatography. A similar material was also used for the preparation of continuous monolithic beds (see below). The applications of superporous agarose are in large-scale purifications.

9.3 Media with Reduced Discontinuity – Membranes, Rolled Sheets, and Monoliths

Although the lowest theoretical interparticular volume of perfectly packed uniformly sized spherical beads is calculated to be about 27% of the total column volume, the void volumes of even the best packed columns are in practice substantially larger. Separation in a medium which is essentially a single piece and does not contain interparticular voids normally contributing to peak broadening has been treated theoretically but experimental work remained scarce as a result of the lack of better alternatives to beads.

The problem of interparticular volume does not exist in systems in which a membrane is used as the separation medium. Both theoretical calculations and experimental results clearly demonstrate that membrane systems can be operated in a dead-end, or filtration mode, at much higher flow rates than packed beds, because all the substrate solution flows through the support and the mass transfer is much faster as a result of this convective flow. Obviously, a reasonable compromise between the membranes with their fast mass transfer and beads with high capacity may result in separation media with enhanced properties.

The simplest available porous membrane is filter paper made of pure cellulose fibers. Numerous modification methods have been described for this material and applications of microcrystalline cellulose powders in chromatography of biopolymers are well known. These may be the most important reasons for the use of modified cellulose sheets (membranes) in various separation devices. As the binding capacity of a single sheet would be too small, commercial membrane cartridges contain several membranes stacked and placed in specifically designed cartridges. The pore size of these membranes is an important variable that effects the separation of proteins. As a result of their large width and low height, membrane cartridges allow for high volumetric throughputs at low back-pressure. The residence time within the cartridge is generally short and thus the danger of denaturation of biopolymers during the separation process is largely reduced. Numerous analytical and preparative separations of proteins in various chromatographic modes have been performed in membrane cartridges with very good results.

Theory predicts a dramatic increase in efficiency for adsorptive membrane devices compared to that of beds packed with particles, perhaps by a factor of 10. However, the nonuniform flow and dead volumes typical of many current cartridges do not fully utilize the intrinsic separation ability of the membranes, and therefore their design must be improved to compete successfully with packed columns. The problem of distorted flow and voids between the membranes in the stack does not exist in cartridges that accommodate only a single thicker disk of porous material. Additionally, Belenki’s theory of critical distance in adsorption chromatography leads to a conclusion that even a very short layer of a separation medium such as the disk can be sufficient for an efficient separation of large molecules. These provisions led to the development of rigid disks for rapid chromatography of biopolymers in the late 1980s.

Flat slabs and rods of porous material are easily prepared in a single step by free-radical polymerization within a closed mold. Disks are cut with a blade from the sheets or machined from the rod and placed into special cartridges. If needed, the porous material can be provided with desired functionalities by chemical modification. Typically, the molded material is wetted with the solution of a reagent and the modification is performed in a flask. Josic et al. studied numerous applications of rigid macroporous disks and found that a well-designed cartridge in combination with optimized disks dramatically improved the performance and allowed for a rapid chromatography of proteins. The separations of protein mixtures in different chromatographic modes, such as ion-exchange and hydrophobic interaction, were easily achieved in a few seconds (Figure 76). Macroporous disks using this technology have been commercialized.

Disks of regenerated cellulose provided with ion-exchange functionalities and placed in disposable cartridges are also commercially available. These devices are characterized by very large through-pores that allow direct purification of dirty feedstocks such as homogenized yeast cells at high flow rates.

Ladisch fabricated stationary phases prepared from rolled flat soft materials—woven textile fabric. The cylindrical roll is inserted into a typical HPLC column blank. The number of chemistries is limited by the variety of fibers. Aramid columns behave as a hydrophobic interaction phase, whereas cotton fabrics transformed to an ion-exchange derivative can be used in IEC.
properties than columns packed with less than 1-mm short fibers. As expected, the efficiency (plate height) does not change with flow velocity because the mass transfer is limited by the stationary phase. Kennedy and Paterson used a similar approach and rolled a rod from a paper-like cellulose sheet. After cyanogen bromide or CDI activation, Protein A and Protein G were immobilized onto the cellulose and the column was successfully used for the affinity separation of IgG.

Slightly cross-linked polyacrylamide beads have been known for a few decades as excellent packing for the low-pressure LC of biomacromolecules. The general perception is that their swelling and softness prevent them from use in tall chromatographic columns. However, a study of the resolving power of another packing material, agarose beads, revealed that columns with functional monomers that were packed into columns and compressed to a fraction of their original volume before use in chromatographic separations. Although plugs have a porosity of about 66%, this porosity mainly represents large pores, whereas the highly cross-linked and compressed nodules are nonporous for proteins. Therefore, separations of large molecules are rather fast. This technology was later extended to the preparation of microcolumns. Materials for chromatographic separations in different modes are obtained either directly by copolymerization that involve different charged or hydrophobic monomers or using in-situ modifications. These compressed beds are now commercialized.

Both quaternary ammonium and sulfonic acid columns for IEC are claimed to have good stability and a high dynamic binding capacity that does not change with an increase in flow velocity. For example, the strong cation-exchange type binds 42 mg of bovine IgG per milliliter of column volume.

Another procedure in which rigid macroporous materials of any desired shape are prepared in their final size is in situ polymerization, developed in the early 1990s. As can be implied, these separation media are not packed but molded within the confines of the tube of a chromatographic column. In this procedure, the column tube (sealed at one end) is filled with the polymerization mixture; then it is sealed at the other end and heated in a water bath. Once the polymerization is complete, the seals are removed and the column is provided with fittings, attached to the HPLC system, and washed. Obviously, an ideal monolith should contain both large pores to achieve a mobile phase flow through the column at a reasonable back-pressure (convection), and a connected network of shorter and smaller pores for diffusion. Indeed, an extensive study of the effects of individual variables of bulk polymerization on the porous properties of products, with particular attention paid to temperature (polymerization kinetics) and porogen composition (phase separation process), led to highly porous monolithic materials with a bimodal pore size distribution that is completely different from that found for macroporous beads prepared from identical polymerization mixtures. Typically, these monoliths contain not only small diffusive pores, but also a large number of flow-through pores with diameters in the range of 700 to 2000 nm. This structure accelerates mass transfer of the sample within the porous material by convection, resulting in faster chromatographic runs without sacrificing the separation power of the monolithic column.

Poly(styrene–divinylbenzene) monoliths are well suited for the rapid separation of proteins in the RP mode with an efficiency on par with micropellicular materials, although at a substantially lower back-pressure (Figure 77). An application showing the potential of this concept is the preparation of monolithic styrene–divinylbenzene in pulled electrospray needles, enabling separation and direct on-line determination of peptides in an MS system with low background noise. Rigid reactive poly(glycidyl methacrylate–ethylene dimethacrylate) monoliths can be easily...

9.4 Temperature-responsive Chromatography

A significant recent trend in biological macromolecule separations is the use of interaction surfaces capable of undergoing rapidly and controlled morphological changes in response to changes in their environment, which in turn alters the interaction characteristics. The best studied of these phenomena are the intra- and intermolecular interactions of side-chains of linear synthetic polymers, which in some polymers carrying side-chains of suitable polarity and shape causes an abrupt temperature-dependent morphological transition known as a critical solution temperature transition. In response to increased temperature, these transitions can be both expansion–dissolution and contraction–precipitation. The distinct temperature-dependent phase phenomena observed for biopolymers, such as thermoreversibility of agarose and gelatin gels, and the melting of double-stranded DNA, are examples of critical solution temperature behavior. These kinds of reversible changes can be utilized in temperature-responsive chromatography.

The best known example of a temperature-responsive synthetic polymer is poly(N-isopropylacrylamide) (poly(NIPAAm)). Its thermal responsiveness has

to the separation of insulin at a high flow velocity of 5 mm s\(^{-1}\).\(^{911}\) This excellent performance appears to arise primarily from the specific morphology of these materials, which have an unusually high level of pore connectivity and possess a larger volume of mesopores (Figure 78).

Among the numerous advantages of monolithic columns are their ruggedness, the versatility of their chemistries, and their excellent efficiency in the separation of biological and synthetic molecules.
found use in immunoassay,\(^{912}\) for modulating\(^{913}\) and mimicking\(^{914}\) enzyme activity, in electrochemical biosensor technology,\(^{915}\) and in LC.\(^{916-918}\) The characteristic that makes poly(NIPAAm) particularly interesting is the convenient location of the lower critical solution temperature at 32°C, where drastic changes of the retention properties are observed.\(^{128}\) The isopropyl group of NIPAAm has a hydrophobic character well suited for the HIC separation of proteins. This application was verified on a continuous-bed sorbent\(^{919}\) and grafted layers on controlled pore glass\(^{920}\) (Figure 79). The temperature-controlled retention allows the HIC separations to proceed with isocratic eluents, thus excluding the tedious equilibration with the starting mobile phase typical of gradient elutions.

Kanazawa et al., Anal. Chem., 69, 829 (1997) by permission of the American Chemical Society.)](image)

### 9.5 Molecularly Imprinted Stationary Phases

Molecularly imprinted polymers (MIPs), conceptualized by Pauling as early as 1940,\(^ {921}\) have been the subject of systematic studies since the 1970s.\(^ {922}\) The driving force for pursuing MIPs as HPLC matrices is to prepare stationary phases with the ultimate selectivity – recognition of a single molecular species. This is accomplished by polymerization of a mixture of monomers around a template molecule, so that the three-dimensional shape of the template is imprinted in the polymer structure. The technique relies upon polar groups in the template being able to organize complementary functional groups on the monomers prior and during solidification of the system. This spatial organization is subsequently frozen by a dense cross-linking. The polymer block is thereafter ground and the template molecules extracted from the pores. The empty cavities have an ability to selectively sequester the template molecules and the spatially organized imprint can recognize chirality. The utility of MIP sorbents has mainly been demonstrated in the separation of racemic mixtures of small chiral compounds.\(^ {923}\) Although Pauling foresaw the preparation of “synthetic antibodies”, it has not yet been possible to prepare MIPs with recognition capabilities for biomacromolecules approaching those found in biological systems. As recognition depends on sequential formation and breaking of several interaction points located in exactly shaped cavities, sorption and desorption reactions in sterically restricted locations become rate-limiting steps and the kinetics of current MIPs is therefore slow. Site inhomogeneity producing severe tailing is also often seen in demonstrated separations. Judging from the large numbers of reviews that have been published recently,\(^ {923-929}\) MIPs have not lost their appeal. However, the persistent challenges in their development are to obtain recognition for large molecules, and to accelerate the interaction kinetics. It appears that radically different designs of MIPs are needed to obtain recognition of biomacromolecules.\(^ {930}\)

### 9.6 Restricted Access Media

Restricted access media (RAM), also known as internal-surface reversed-phase (ISRP) sorbents, are porous beads where the functionalization of the perimeter is different from the internal pore system. The outward-facing surface of the particle is typically hydrophilic, whereas the inner surface is hydrophobic or carrying groups for specific interactions with solutes capable of entering the porous system.\(^ {931}\) They can be considered as mixed-mode sorbents with spatially segregated hydrophobicity controlled by a size-exclusion mechanism. Such materials are obviously not very useful for separation of biological macromolecules but their utility in separation
schemes for large molecules lies in the possibility of selectively interacting with small molecules that should be removed from macromolecules.\(^{(92)}\) Internal-surface materials have also proven useful in the separation of cyclic peptides.\(^{(235)}\)

**10 CONCLUSIONS**

It is virtually impossible to provide a complete and nuanced overview of an area as vast as the one covered by this article. Yet, it has hopefully been possible to communicate not only the basic problems associated with separation of biological macromolecules in LC, but also the possibilities created by recent developments in the area. An important distinction must be made between analytical separations and micro- or macro preparative separations by HPLC, a gap that has been narrowed through modern materials that merge soft separation techniques previously reserved for slow preparative separations into the HPLC format. The major tradeoffs are, as always, between separation efficiency, separation time, and capacity. A recurring issue has been ways of preventing denaturing, i.e. to preserve biological activity of the separated substances. Again, this issue is usually more important to biochemists than to analytical chemists, as long as the separation techniques are capable of resolving the solutes and presenting them to the detector in a form which allows identification and quantification. Although separation chemistries have been treated as if they were entirely separate from each other, biomacromolecules are themselves governing the interaction modes to a large extent. Their chromatographic behaviors are therefore usually a mix between different separation modes, where the combined properties of the solute, the support, the interaction groups, and the eluent are interacting in providing a retention according to a multitude of interaction mechanisms. By having provided abbreviated descriptions of each of these modes, the reader should be better prepared to make all the choices required in developing a method. However, in the end all biological macromolecules are unique, and any generalization is prone to fail when faced with the immense variability of biological systems.

**ACKNOWLEDGMENTS**

The author is greatly indebted to Frantisek Švec for carefully reading and commenting on most parts of the manuscript, as well as for providing a textual input on continuous separation media.

HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY OF BIOLOGICAL MACROMOLECULES

Infrared (IR) spectroscopy has been a powerful tool for studying biological molecules and the application of this technique to biological problems is continually expanding, particularly with the advent of Fourier Transform Infrared (FTIR) spectroscopy in recent decades. One of the great advantages of IR spectroscopy is that virtually any sample in virtually any state can be studied. Liquids, solutions, pastes, powders, films, fibers, gases and surfaces can all be examined with a judicious choice of sampling technique. Biological systems such as proteins, peptides, lipids, biomembranes, carbohydrates, pharmaceuticals, foods and both plant and animal tissues have all been successfully characterized using IR spectroscopy.\(^{1-4}\)

IR spectrometers have been commercially available since the 1940s. At that time the instruments relied on prisms to act as dispersive elements, but by the mid 1950s, diffraction gratings had been introduced into dispersive machines. The most significant advances in IR spectroscopy, however, have come about with the introduction of Fourier transform spectrometers. This type of instrument employs an interferometer and exploits the well established mathematical process of Fourier transformation. FTIR spectroscopy has dramatically improved the quality of IR spectra and minimized the time required to obtain data. Also, with improvements to computers in recent years, IR spectroscopy has made great strides.

1 INTRODUCTION

In recent years FTIR spectroscopy has found increasing favor in laboratories.\(^{1,2}\) This more recent method is based on the old idea of the interference of radiation between two beams to yield an interferogram. An interferogram is a signal produced as a function of the change of pathlength between the two beams. The two domains of distance and frequency are interconvertible by the mathematical method of Fourier transformation. Although the basic optical component of FTIR instruments, the Michelson interferometer, has been known for almost a century, it was not until advances in computing that the technique could be successfully applied. The basic components of a FTIR spectrometer are shown schematically in Figure 1.

The most common interferometer used is a Michelson interferometer, and consists of two perpendicularly plane mirrors, one of which can travel in a direction perpendicular to the plane (Figure 2). A semi-reflecting film, the beam splitter, bisects the planes of these two mirrors. If a collimated beam of monochromatic radiation of wavelength \(\lambda\) cm is passed into an ideal beam splitter, 50% of the incident radiation will be reflected to one of the mirrors and 50% will be transmitted to the other mirror. The beam which emerges from the source is passed through an interferometer to the sample before reaching a detector. Upon amplification of the signal, in which high frequency contributions have been eliminated by a filter, the data are converted to a digital form by an analog-to-digital converter and transferred to the computer for Fourier transformation.

The most common interferometer used is a Michelson interferometer, and consists of two perpendicularly plane mirrors, one of which can travel in a direction perpendicular to the plane (Figure 2). A semi-reflecting film, the beam splitter, bisects the planes of these two mirrors. If a collimated beam of monochromatic radiation of wavelength \(\lambda\) cm is passed into an ideal beam splitter, 50% of the incident radiation will be reflected to one of the mirrors and 50% will be transmitted to the other mirror. The two beams are reflected from these mirrors, returning to the beam splitter where they recombine and interfere. Fifty percent of the beam reflected from the fixed mirror is transmitted through the beam splitter and 50% is reflected back in the direction of the source. The beam which emerges from the interferometer at 90° to the input beam is called the transmitted beam and this is the beam detected in FTIR spectrometry.
2 SAMPLING METHODS

IR spectroscopy is a versatile experimental technique and it is relatively easy to obtain spectra from biological samples in solution or the solid state. In this section we shall study how samples can be introduced into the instrument, the equipment required to obtain spectra and the pretreatment of samples will be discussed.

2.1 Transmission Methods

Transmission spectroscopy is the oldest and most basic IR method. The method is based upon the absorption of IR radiation at specific wavelengths as it passes through a sample. Liquid or solid forms can be analyzed using this technique.

There are several different types of transmission solution cells available. Fixed pathlength sealed cells are useful for volatile liquids, but cannot be taken apart for cleaning. Semi-permanent cells are demountable so that the windows can be cleaned. A semi-permanent cell is illustrated in Figure 4. The spacer is usually made of polytetrafluoroethylene (PTFE, Teflon) and is available in a variety of thicknesses, allowing one cell to be used for various pathlengths. Variable pathlength cells incorporate a mechanism for continuously adjusting the pathlength and a vernier scale allows accurate adjustment. All these cell types are filled using a syringe and the syringe ports are sealed with PTFE plugs before sampling. An important consideration in the choice of IR cells is the type of window material. The material

must be transparent to the incident IR radiation and normally alkali halides are used in transmission methods. The cheapest material is sodium chloride (NaCl), but other commonly used materials are listed in Table 1. Liquid films provide a quick method of examining liquid samples. A drop of liquid may be sandwiched between two IR plates which are then mounted in a cell-holder. The type of spectrum expected from a liquid film is illustrated in Figure 5, which shows the spectrum of chloroform, a solvent commonly used for biological samples.

Before producing an IR sample in solution, a suitable solvent must be chosen. In choosing a solvent there is a number of factors to be considered. A solvent must obviously be able to dissolve the compound. It should also be as nonpolar as possible to minimize solute–solvent interactions. In addition, the solvent should not strongly absorb IR radiation. If quantitative analysis is required it is necessary to use a cell of known pathlength. A guide to pathlength selection for different solution concentrations is shown in Table 2.

Water is a commonly used solvent for biological samples and NaCl cannot be used as an IR window material as it is very soluble in water. Small pathlengths (~0.010 mm) are available and help reduce the intensity of the very strong IR modes produced in the water spectrum. The small pathlength also produces a small sample cavity, allowing samples in milligram quantities to be examined. Certain difficulties arise when using water as a solvent in IR spectroscopy. The IR modes of water are very intense and may overlap with the sample modes of interest. This problem may be overcome by substituting water with deuterium oxide (D₂O). The IR modes of D₂O occur at different frequencies to those observed for water because of the mass dependence of the vibrational frequency. Table 3 lists the characteristic bands observed for both H₂O and D₂O.

There are three general methods for examining solid samples in transmission IR spectroscopy: alkali halide discs, mulls and films. A choice of method depends very much on the nature of the sample to be examined. The use of alkali halide discs involves mixing a solid sample (a few mg) with a dry alkali halide powder (100–200 mg). The mixture is usually ground with an agate mortar and pestle and subjected to a pressure of about 10 ton in⁻² (1.575 × 10⁵ kg m⁻²) in an evacuated die. This sinters the mixture and produces a clear transparent disc. The most commonly used alkali halide is potassium bromide (KBr), which is completely transparent in the mid-IR region.

Certain factors need to be considered when preparing alkali halide discs. The ratio of the sample to alkali halide is important. Surprisingly little sample is needed and approximately 2 to 3 mg of sample with about 200 mg of halide should be used. The disc must not be too thick or too thin. Thin discs are fragile and difficult to handle, while thick discs transmit too little radiation. A disc of about 1 cm diameter made from about 200 mg of material usually results in a good thickness of about 1 mm. If the crystal size of the sample is too large excessive scattering of radiation results, particularly so at high wavenumbers. The crystal size must be reduced, normally by grinding the solid using a mortar and pestle. If the alkali halide is not perfectly dry this results in the appearance of bands due to water. Contributions due to water are difficult to avoid, and the alkali halide should be kept desiccated and warm prior to use.

The preparation of mulls for solid samples involves grinding the sample then suspending it (about 50 mg) in 1–2 drops of a mulling agent. This is followed by further grinding until a smooth paste is obtained. Ideally a mulling agent should be IR transparent between 4000 and 600 cm⁻¹, but no such agent exists. The most commonly used mulling agent is liquid paraffin (Nujol®), and its

Figure 6 The IR spectrum of chloroform.

Figure 5 The IR spectrum of chloroform.

spectrum is shown in Figure 6. Although the mull method is quick and easy, there are some points to consider. The ratio of the sample to mulling agent must be appropriate as if there is too little sample and there will be no sign of the sample in the spectrum. Too much sample and a thick paste will be produced and no radiation will be transmitted. A rough guide to mull preparation is to use a micro spatula tip of sample to 2–3 drops of mulling agent. If the crystal size of the sample is too large this leads to scattering of radiation, which gets worse at the high frequency end of the spectrum. If the mull is not spread over the whole plate area, the beam of radiation passes part through the mull and part through only the plates, producing a distorted spectrum. Care should also be taken not to use too much or too little mull between the IR plates. Too little leads to a very weak spectrum showing only the strongest absorption bands. Too much mull leads to poor transmission of radiation so that the baseline may be at 50% or less. It is sometimes possible to reduce the energy of a reference beam to a similar extent by use of an attenuator. Beam attenuators work somewhat like a venetian blind, illustrated by Figure 7.

Films can be produced by either solvent casting or by melt casting. In solvent casting the sample is dissolved in an appropriate solvent (the concentration depends on the required film thickness). A solvent must be chosen which not only dissolves the sample, but will also produce a uniform film. The solution is poured onto a leveled glass plate (such as a microscope slide) or a metal plate and spread to uniform thickness. The solvent may then be evaporated in an oven and, once dry, the film can be stripped from the plate. However, care must be taken
as heating biological samples may cause degradation. Alternatively, it is possible to cast a film straight onto the IR window to be used. Solid samples which melt at relatively low temperatures without decomposition can be prepared by melt casting. A film is prepared by hot pressing the sample in a hydraulic press between heated metal plates.

2.2 Reflectance Methods

Reflectance techniques can be used for samples which are difficult to analyze by the normal transmittance methods. Reflectance methods can be divided into two categories. Internal reflectance measurements can be made using an attenuated total reflectance (ATR) cell in contact with the sample. There are also external reflectance measurements which involve an IR beam reflected directly from the sample surface.

ATR spectroscopy utilizes the phenomenon of total internal reflection (Figure 8). A beam of radiation entering a crystal will undergo total internal reflection when the angle of incidence at the interface between the sample and crystal is greater than the critical angle. The critical angle is a function of the refractive indices of the two surfaces. The beam penetrates a fraction of a wavelength beyond the reflecting surface and when a material which selectively absorbs radiation is in close contact with the reflecting surface, the beam loses energy at the wavelength where the material absorbs. The resultant attenuated radiation is measured and plotted as a function of wavelength by the spectrometer and gives rise to the absorption spectral characteristics of the sample. The depth of penetration in ATR is a function of wavelength \((\lambda)\), the refractive index of the crystal and the angle of incident radiation \((\theta)\). The depth of penetration, \(d_p\), for a nonabsorbing medium is given by Equation (1):

\[
d_p = \frac{\lambda / n_1}{2\pi \sin \theta - (n_1/n_2)^2}^{1/2}
\]

where \(n_1\) is the refractive index of the sample and \(n_2\) is the refractive index of the ATR crystal. The crystals used in ATR cells are made from materials which have low solubility in water and are of very high refractive index. Such materials include zinc selenide (ZnSe), germanium
(Ge) and thallium/iodide (KRS-5). The properties of these commonly used materials for ATR crystals are summarized in Table 4. Different designs of ATR cells allow both liquid and solid samples to be examined. It is also possible to set-up a flow-through ATR cell by including an inlet and outlet into the apparatus. This allows for continuous flow of solutions through the cell and permits spectral changes with time to be monitored. Multiple internal reflectance (MIR) and ATR are similar techniques, but MIR produces more intense spectra from multiple reflections. While a prism is usually used in ATR work, MIR uses specially shaped crystals which cause many internal reflections, typically 25 or more (Figure 9).

In external reflectance incident radiation is focused onto the sample and two forms of reflectance can occur: specular and diffuse. External reflectance measures the radiation reflected from a surface. The material must, therefore, be reflective or be attached to a reflective backing. A particularly useful application for this technique is the study of surfaces.

Specular reflectance occurs when the reflected angle of incident radiation equals the angle of incidence (Figure 10). The amount of light reflected depends on the angle of incidence, the refractive index, surface roughness and absorption properties of the sample. For most materials the reflected energy is only 5–10%, but in regions of strong absorptions the reflected intensity is greater. The resultant data appears different from normal transmission spectra, as derivative-like bands result from the superposition of the normal extinction coefficient spectrum with the refractive index dispersion (based upon Fresnel’s relations from physics). However, the reflectance spectrum can be corrected using a Kramers–Kronig transformation (or K–K transformation). The corrected spectrum appears like the familiar transmission spectrum.

Increased pathlengths through thin coatings can be achieved using grazing angles of incidence (up to 85°). Grazing angle sampling accessories allow measurements to be made on samples over a wide range of angles of incidence. Solid samples, particularly coatings on reflective surfaces, are simply placed on a flat surface. The technique is also commonly used for liquid samples which can be poured into a PTFE trough. Oriented films on the liquid surface can be investigated using this material. The grazing angle approach can be used to study surfactants, proteins, steroids and phospholipids in biological membranes.

In external reflectance, the energy which penetrates one or more particles is reflected in all directions. This component is called diffuse reflectance. In the diffuse reflectance infrared technique, commonly called (DRIFT), a powdered sample is mixed with KBr powder. The DRIFT cell reflects radiation to the powder and collects the energy reflected back over a large angle.

**Figure 9** A MIR cell.

**Figure 10** Specular reflectance.
Diffusely scattered light can be collected directly from a sample or, alternatively, using an abrasive sampling pad. DRIFT is particularly useful for sampling powders or fibers. Figure 11 shows diffuse reflectance from the surface of a sample. Kubelka and Munk developed a theory describing the diffuse reflectance process for powdered samples which relates the sample concentration to the scattered radiation intensity. The Kubelka–Munk equation is Equation (2):

\[
\frac{(1 - R_{\infty})^2}{2R_{\infty}} = \frac{c}{k}
\]

(2)

where \(R_{\infty}\) is the absolute reflectance of the layer, \(c\) is the concentration and \(k\) is the molar absorption coefficient. Figure 12 shows the diffuse reflectance spectrum of aspirin. An alternative relationship between the concentration and the reflected intensity is now widely used in near-IR diffuse reflectance spectroscopy. The relationship is analogous to the Beer–Lambert law (Equation 3):

\[
\log \left( \frac{1}{R} \right) = k'c
\]

(3)

where \(k'\) is a constant.

2.3 Microsampling Methods

It is possible to combine an IR spectrometer with a microscope facility in order to study very small quantities. In recent years there have been considerable advances in FTIR microscopy with samples as small as 25 µm being characterized. In FTIR microscopy, the microscope sits above the FTIR sampling compartment. IR radiation from the spectrometer is focused onto a sample placed on a standard microscope x–y stage. After passing through the sample, the IR beam is collected by a Cassegrain objective which produces an image of the sample within the barrel of the microscope. A variable aperture is placed in this image plane. The radiation is then focused on a small area mercury cadmium telluride detector by another Cassegrain condenser. The microscope also contains glass objectives to allow visual inspection of the sample. In addition, by switching mirrors in the optical train, the microscope can be converted from transmission mode to reflectance mode.

If a microscope facility is not available, there are other special sampling accessories available to allow examination of microgram or microlitre amounts. This is accomplished using a beam condenser so that as much as possible of the beam passes through the sample. Microcells are available with volumes of around 4 µL and pathlengths up to 1 mm.

There are a number of microsampling cells available. A diamond anvil cell (DAC) uses two diamonds to compress a sample to a thickness suitable for measurement and increase the surface area. This technique can be used at normal atmospheric pressures, but it may also be applied to study samples under high pressures and improve the quality of the spectrum of trace samples.

A MIR cell can also be used as this technique can produce strong spectra. The ability to obtain spectra from trace amounts of materials is illustrated in Figure 13.
which shows the IR spectra of the pain relieving drug phenacetin deposited onto a micro MIR crystal.

2.4 Gas Chromatography/Infrared

IR spectroscopy has been combined with various other analytical techniques. Gas chromatography/infrared spectroscopy (GC/IR) allows the identification of the components eluting from gas chromatography (GC). GC/IR has certain advantages over, say, gas chromatography/mass spectrometry (GC/MS). While GC/MS is able to distinguish easily between compounds of different mass, it is unable to differentiate structural isomers of the same molecular mass. By comparison, GC/IR can easily distinguish isomers.

Figure 14 shows a schematic diagram of a typical combining system GC with FTIR. The apparatus consists of a FTIR spectrometer, a gas chromatograph, light pipe, detector and a computer for analysis. The light pipe interfaces the GC with the spectrometer. The pipe is usually made of quartz and should be approximately one-half the width of the GC peaks for the best compromise between chromatographic resolution and IR sensitivity. For capillary column GC, the light pipe usually has a 1 mm inner diameter and for packed columns a light pipe of inner diameter 2–3 mm is used.

The nature of this technique requires that interferograms are collected in short time intervals. Gram–Schmidt chromatograms are created from the interferogram intensities and reflect the IR absorption. The Gram–Schmidt traces are a plot of IR absorbance versus time. The absorbance spectra of the eluted species are calculated by performing a Fourier transformation on the interferogram.

IR spectroscopy has been combined with other established analytical techniques. For instance, with thermogravimetric analysis (TGA) which is a technique which involves measuring the change of mass of a sample when it is heated. While TGA can provide quantitative information about a decomposition process, it is unable to identify the decomposition products. However, TGA and IR have been combined to provide a complete qualitative and quantitative characterization of thermal decomposition processes.

2.5 Temperature Cells

Variable temperature cells can be obtained which are controlled to 0.1 °C in the range −180 to 250 °C. An electrical heating system is used for temperatures above ambient, and liquid nitrogen with a heater for low temperatures. These cells can be used to study phase transitions and the kinetics of reactions. As well as transmission temperature cells, variable temperature ATR cells and cells for microsampling are available.

3 SPECTRUM INTERPRETATION

Spectrum interpretation is simplified by the fact that the bands which appear can be assigned to particular parts of the molecule, producing what are known as group frequencies. The mid-IR region is normally treated as four regions, depending upon the type of group frequency. However, of certain factors which complicate IR spectra. Phenomena such as overtone and combination bands, Fermi resonance and hydrogen bonding can introduce additional, and sometimes misleading, information into the spectrum. It is important to be aware of these factors before tackling the interpretation of a given spectrum.

3.1 Group Frequencies

The mid-IR spectrum can be divided into four regions and the nature of a group frequency may generally be determined by the region in which it is located. These regions are defined as follows:

1. X–H stretching region (4000–2500 cm⁻¹)
2. triple bond region (2500–2000 cm⁻¹)
3. double bond region (2000–1500 cm⁻¹)
4. fingerprint region (1500–600 cm⁻¹).

All the fundamental vibrations in the region 4000–2500 cm⁻¹ may be attributed to X–H stretching. O–H stretching produces a broad band which occurs in the
range 3700–3600 cm\(^{-1}\). By comparison, N–H stretching is usually observed between 3400 and 3300 cm\(^{-1}\). This absorption is generally much sharper than O–H stretching and may therefore be differentiated. Compounds containing the NH\(_2\) group usually show a doublet structure, while secondary amines show one sharp band. C–H stretching bands from aliphatic compounds occur in the range 3000–2850 cm\(^{-1}\). They are moderately broad and show medium intensity. It is also possible to resolve asymmetrical and symmetrical C–H stretching absorptions of a CH\(_2\) group which usually occur at about 2965 and 2880 cm\(^{-1}\), respectively, while the corresponding absorptions for a CH\(_3\) group occur at 2930 and 2860 cm\(^{-1}\). If the C–H bond is adjacent to a double bond or aromatic ring, the C–H stretching frequency increases and absorbs between 3100 and 3000 cm\(^{-1}\). This is useful in distinguishing purely aliphatic compounds, but must be used with care as for many compounds containing a small number of aromatic hydrogens and many aliphatic C–H bonds the peaks above 3000 cm\(^{-1}\) may only appear as a shoulder on the stronger aliphatic absorption and may be obscured. However, evidence for the presence of an aromatic ring may be obtained by examination of other regions of the spectrum. Deuterated compounds would be expected to show C–D stretching at a factor of 0.73 less due to the change in atomic mass. That is, at about 2130 cm\(^{-1}\).

Triple bond stretching absorptions fall in the 2500–2000 cm\(^{-1}\) region because of the high force constants of the bonds. C≡C bonds absorb between 2300 and 2050 cm\(^{-1}\), while the nitrile group (C≡N) occurs between 2300 and 2200 cm\(^{-1}\). These groups may be distinguished since C≡C stretching is normally very weak, while C≡N stretching is of medium intensity. These are the most common absorptions in this region, but you may come across some X–H stretching absorptions, where X is a more massive atom like phosphorus or silicon. These absorptions usually occur near 2400 and 2200 cm\(^{-1}\), respectively.

The principal bands in the 2000–1500 cm\(^{-1}\) region are due to C=C and C=O stretching. Carbonyl stretching is one of the easiest absorptions to recognize in an IR spectrum. It is usually the most intense band in the spectrum, and depending on the type of C=O bond, occurs in the region 1830–1650 cm\(^{-1}\). Note also that metal carbonyls may absorb above 2000 cm\(^{-1}\). C=C stretching is much weaker and occurs at around 1650 cm\(^{-1}\). This band is often absent for symmetry or dipole moment reasons. C=N stretching also occurs in this region and is usually stronger. The N–H bending vibration in amines occurs between 1630 and 1500 cm\(^{-1}\) and is usually strong. Before assigning a band always check the N–H stretching region above 3000 cm\(^{-1}\) to avoid possible confusion.

At frequencies of values greater than 1500 cm\(^{-1}\) it is generally possible to assign each absorption band in an IR spectrum. This is not so for most absorptions observed below 1500 cm\(^{-1}\). This region is referred to as the fingerprint region, since quite similar molecules give different absorption patterns at these frequencies.

It has been assumed so far that each band in an IR spectrum can be assigned to a particular deformation of the molecule, the movement of a group of atoms or the bending or stretching of a particular bond. This is possible for many bands, particularly stretching vibrations of multiple bonds which are well behaved. However, many vibrations are not so well behaved and may vary by hundreds of wavenumbers even for similar molecules. This applies to most bending and skeletal vibrations, which absorb in the 1500–650 cm\(^{-1}\) region, for which small steric or electronic effects in the molecule lead to large shifts. A spectrum of a molecule may have a hundred or more absorption bands present, but there is no need to assign the vast majority. The spectrum can be regarded as a ‘fingerprint’ of the molecule. Most single bonds absorb at similar frequencies and hence the vibrations couple. The observed pattern will depend on the carbon skeleton, and the resulting bands will originate from the oscillation of large parts of the skeleton, or the skeleton and the attached functional groups. C–C stretching frequencies may also couple with C–H bending vibrations. The C–O stretching frequency is one of the bands that can be useful for identification purposes. If no intense band appears in the fingerprint region, you can usually be sure that no C–O bonds are present. The frequency is rather variable, occurring anywhere between 1400 and 1000 cm\(^{-1}\). Aromatic rings give rise to two bands at 1600 and 1500 cm\(^{-1}\). They are usually sharp, but are of variable intensity and occasionally the band at 1600 cm\(^{-1}\) splits into a doublet. Aromatic rings and alkenes give rise to other bands which are perhaps the most useful in this region. They are out-of-plane C–H bending vibrations which occur between 1000 and 700 cm\(^{-1}\).

The information provided by group frequencies can be summarized in what are known as a correlation tables. Figure 15 shows a correlation table for organic molecules. The lines in the correlation table represent the regions of the spectrum where bands appear for the relevant class of molecule.

3.2 Complicating Factors

Although it is a useful assumption to be make, it is not true that all bands in a spectrum can simply be associated with a particular bond or part of a molecule. Certain complicating factors need to be taken into account. One such factor is the presence of overtone and combination bands. Overtone bands in an IR spectrum are multiples of the fundamental absorption frequency. The energy levels for overtones of IR modes are illustrated in Figure 16. The
**Figure 15** A correlation table for organic molecules.

Energy required for the first overtone is twice the fundamental, assuming evenly spaced energy levels. Since the energy is proportional to the frequency absorbed and this is proportional to the wavenumber, the first overtone will appear in the spectrum at twice the wavenumber of the fundamental. Combination bands arise when two fundamental bands absorbing at \( \tilde{v}_1 \) and \( \tilde{v}_2 \) absorb energy simultaneously. The resulting band will appear at \((\tilde{v}_1 + \tilde{v}_2)\) wavenumbers. The absorptions observed in the near-IR region (13 000–4000 cm\(^{-1}\)) are overtones or combinations of the fundamental stretching bands that occur in the region 3000–1700 cm\(^{-1}\). The bands involved are usually due to C–H, N–H, O–H, P–H or S–H stretching. The resulting bands in the near-IR are usually weak in intensity and the intensity generally decreases by a factor of 10 from one overtone to the next. The bands in the near-IR are often overlapped, making them less useful than the mid-IR region for qualitative analysis. However, there are important differences between the near-IR positions between functional groups and these differences can often be exploited for quantitative analysis. There are some classes of biological materials which can be successfully analyzed using near-IR spectroscopy, such as foods.

The Fermi resonance effect usually leads to two bands appearing close together when only one is expected.

![Figure 16](image-url) **Figure 16** Energy levels for fundamental and overtone IR bands.

When an overtone or a combination band has the same frequency as or a similar frequency to a fundamental, two bands appear split either side of the expected value and are of about equal intensity. The effect is greatest when the frequencies match, but it is also present when there is a mismatch of a few tens of wavenumbers. The two bands are referred to as a Fermi doublet.

The presence of hydrogen bonding is of great importance in biological molecules. For instance, the biological activity of DNA relies on this type of bonding. Hydrogen bonding can be defined as the attraction which occurs between a highly electronegative atom carrying a nonbonded electron pair (such as fluorine, oxygen or nitrogen) and a hydrogen atom, itself bonded to a small highly electronegative atom. An example of this type of bonding is illustrated by the interactions between...
Hydrogen bonding is a very important effect in IR spectroscopy. In IR spectroscopy the frequencies of vibration of bonds depend on the masses of the atoms in the bond and the bond stiffness. Hydrogen bonding influences the bond stiffness and so alters the frequency of vibration. For example, for a hydrogen bond in an alcohol, the O–H stretching vibration in a hydrogen bonded dimer is observed in the range 3500–2500 cm\(^{-1}\), rather than the usual range 3700–3600 cm\(^{-1}\) (Figure 19). Apart from solvent effects, concentration and temperature also affect the degree of hydrogen bonding in a compound. The lower the concentration, the less chance there is of two molecules colliding. It follows that the degree of hydrogen bonding decreases with decreasing concentration. Increasing temperature means that each molecule will have more energy on average and hence weak associative forces, such as hydrogen bonds, are likely to be broken. This should lead to a lesser degree of hydrogen bonding, and thus changes in frequency to greater values would be observed for groups forming the hydrogen bond.

Another issue to be considered is coupling. Vibrations in the skeleton of molecules become coupled. In other words, they are not restricted to one or two bonds, but may involve a large part of the carbon backbone and oxygen or nitrogen atoms if present. The energy levels mix, resulting in the same number of vibrational modes, but at different frequencies, and bands can no longer be assigned to one bond. This is very common and occurs when adjacent bonds have closely similar frequencies. Coupling commonly occurs between C–C stretching, C–O stretching, C–N stretching, C–H rocking and C–H wagging motions. A further requirement is that to be strongly coupled the motions must be in the same part of the molecule. There are three factors which determine whether coupling will take place: the groups must be adjacent; the frequencies must be similar; and the vibrations must be in the same part of the molecule. It turns out that all vibrations which absorb in the region 1500–650 cm\(^{-1}\) will couple to an extent that critically depends on the shape of the molecule. Large groups, the presence of double and triple bonds and electronic effects will influence coupling. Hence it is difficult to predict the extent of this coupling and this leads to great difficulties in the assignment of bands in this region of the spectrum. This phenomenon accounts for the wide range of frequencies over which C–C, C–O and C–N stretching vibrations absorb. The most important consequence of coupling is that small changes in structure leads to major changes in the IR spectrum in the 1500–650 cm\(^{-1}\) region. It is very unlikely, therefore, that two different molecules will have exactly the same pattern of bands in this region.

3.3 Identification of Unknown Materials

There are a few general rules that can be stated to help in the use of an IR spectrum for the determination of a structure. However, the most effective way to learn is through practice. The following is a suggested strategy for spectrum interpretation:

1. Look first at the high-frequency end of the spectrum (>1500 cm\(^{-1}\)) and concentrate initially on the major bands.
2. For each band, short list the possibilities using a correlation chart.
3. Use the lower frequency end of the spectrum for the confirmation or elaboration of possible structural elements.
4. Do not expect to be able to assign every band in the spectrum.
5. Cross-check wherever possible. For example, an aldehyde should absorb near 1730 cm\(^{-1}\) and in the region 2900–2700 cm\(^{-1}\).
6. Exploit negative evidence as well as positive evidence. For example, if there is no band in the 1850–1600 cm\(^{-1}\) region, it is most unlikely that a carbonyl group is present.
7. Band intensities should be treated with some caution. Under some circumstances they may vary considerably for the same functional group.
8. Take care when using small frequency changes. These can be influenced by whether the spectrum was run as a solid or liquid or in solution. Some bands are very solvent sensitive in solutions.
9. Subtract the solvent bands before interpretation – these could be confused with bands from the sample.

Advances in computer retrieval techniques have extended the range of information available from an IR instrument by allowing comparison of an unknown spectrum with a bank of known compounds. This was always possible in the past by manually searching libraries of spectra. Once the compound was classified the atlas of spectra could be searched for an identical or very similar spectrum. The advent of more efficient computers has speeded this search process. Programs widely available work by hunting through stored data to match intensities and frequencies of absorption bands. The computer will then output the best fits and the names of the compounds found. There is a wide range of spectral libraries of particular interest to life scientists. For instance, libraries for the following types of samples are currently available: proteins, peptides, enzymes, sugars, carbohydrates, fatty acids, glycerides, steroids, food additives, drugs and pharmaceuticals.

It may not always be possible by examination of the IR spectrum of a compound alone to identify it unequivocally. It is normal to use IR in conjunction with other techniques, such as chromatographic methods, mass spectrometry (MS), nuclear magnetic resonance (NMR) spectroscopy and the variety of other spectroscopic techniques.

4 QUANTITATIVE ANALYSIS

Quantitative IR spectroscopy suffers certain disadvantages when compared with other analytical techniques and it tends to be confined to specialist applications. However, there are certain applications where it is used because it is cheaper or faster. The technique is often used for the analysis of one component of a mixture, especially when the compounds in the mixture are alike chemically or have very similar physical properties (for example, structural isomers). In these instances analysis using ultraviolet/visible (UV/VIS) spectroscopy is difficult because the spectra of the components will be nearly identical. Chromatographic analysis may be of limited use because separation, of say isomers, is difficult to achieve. The IR spectra of isomers are usually quite different in the fingerprint region. Another advantage of the IR technique is that it is nondestructive and requires only a relatively small amount of sample.

4.1 Spectrum Manipulation

There are a number of techniques available to users of modern IR spectrometers which help with both qualitative and quantitative interpretation of spectra. It is usual in quantitative IR spectroscopy to use a baseline joining the points of lowest absorbance on the peak, preferably in reproducibly flat parts of the absorption line. The absorbance difference between the baseline and the top of the band is then used. A baseline construction is shown in Figure 20.

Noise in a spectrum can be diminished by smoothing. After a spectrum is smoothed it becomes similar to the result of an experiment at a lower resolution. The features are blended into each other and the noise level decreases. A smoothing function is basically a convolution between the spectrum and a vector whose points are determined by the degree of smoothing you choose to apply. Generally, you will be asked to enter a degradation factor, which will be some positive integer. A low value, say one, will produce only subtle changes, while a high value has a more pronounced effect on your spectrum.

The most straightforward method of analysis for complex spectra is difference spectroscopy. Difference spectroscopy can be carried out simply by subtracting
the IR spectrum of one component of the system from the combined spectrum to leave the spectrum of the other component. If the interaction between components results in a change in the structural properties of either one or both of the components, the changes will be observed in the difference spectra. The changes may manifest themselves via the appearance of positive or negative peaks in the spectrum.

Spectral subtraction can be applied to numerous applications and can be used for the data collected for solutions. In order to obtain the spectrum of a solution it is necessary to record spectra of both the solution and the solvent alone. The solvent spectrum may then be subtracted from the solution spectrum. There are two approaches – the solvent alone in the cell may be used as a reference in a double beam dispersive experiment, or the solvent spectrum may be recorded separately and then subtracted if using a single beam instrument. Figure 21, where the strong IR spectrum of water has been removed from a relatively weak spectrum of a 1% w/v solution of aspirin, illustrates how subtraction can be very useful in FTIR spectroscopy. Care must be taken when subtracting spectra. The concentration of the solvent alone is greater than that of the solvent in the solution and negative peaks may appear in the regions of solvent absorption. In certain circumstances, the spectrum due to the solvent may be very intense, making simple subtraction impossible. This situation can make it difficult to investigate the sample spectrum as solvent bands may overlap with the region under investigation. In such experiments, ATR provides a suitable substitute. The nature of the ATR technique produces a less intense solvent contribution to the overall IR spectrum and so solvent spectra can be more readily subtracted from the sample spectrum of interest. Subtraction can also be applied to solid samples and is especially useful for mulls. The spectrum of the mulling agent can be subtracted, giving the spectrum of the solid only.

Spectra can also be differentiated. Figure 22 shows a single absorption peak and its first and second
derivative. Derivative techniques have long been used in quantitative UV/VIS spectroscopy, the benefits of the technique being two-fold. Resolution is enhanced in the first derivative since we are looking at changes in gradient. The second derivative gives a negative peak for each band and shoulder in the absorption spectrum. The advantage of derivatization is more readily appreciated for more complex spectra and Figure 23 shows how differentiation can be used to resolve and locate peaks in an envelope. Note that sharp bands are enhanced at the expense of broad ones and this may allow selection of a peak, even when there is a broad band beneath. With modern FTIR spectrometers it is possible to apply what is known as Fourier derivation. During this process the spectrum is transformed to an interferogram. It is then multiplied by an appropriate weighting function and finally it is retransformed to give the derivative. This technique provides more sensitivity.

Deconvolution is the process of compensating for the intrinsic linewidths of modes in order to resolve overlapping bands. The technique yields spectra that have much narrower bands and is able to distinguish closely-spaced features. The instrumental resolution is not increased, but the ability to differentiate spectral features can be significantly improved. This is illustrated by Figure 24, which shows a broad band before and after deconvolution has been applied. The peaks at quite close frequencies are now easily distinguished. The deconvolution technique generally involves several steps: computation of an interferogram of the sample by computing the inverse Fourier transform of the spectrum; multiplication of the interferogram by a smoothing function and by a function consisting of a Gaussian–Lorentzian band shape; Fourier transformation of the modified interferogram. The deconvolution procedure is typically repeated iteratively for best results. At iteration, the lineshape is adjusted in an attempt to provide narrower bands without excessive distortion. There are three parameters that can be adjusted to tune the lineshape. The proportion of Gaussian and Lorentzian lineshape may be altered. The scale of these components is adjusted depending on the predicted origins of the band shape. For instance, it will vary depending on whether you

![Figure 23](image1.png)

![Figure 24](image2.png)

**Figure 24** A broad IR band before and after deconvolution.
are examining a solid or a liquid or a gas. The half-width is the width of the lineshape and is normally the same as or larger than the intrinsic linewidth (full width at half height) of the band. If the value specified is too small, the spectrum tends to show only small variations in intensity. If too large, distinctive negative side lobes are produced. The narrowing function is the degree of narrowing attempted on a scale 0–1. If specified too small, the resulting spectrum will not be significantly different from the original. If too large, the spectrum may produce false peaks as noise starts to be deconvolved.

Quantitative values for band areas of heavily overlapped bands can be achieved by using curve-fitting procedures. Many curve-fitting procedures are based on a least-squares minimization procedure. Least squares curve-fitting covers the general class of techniques whereby one attempts to minimize the sum of the squares of the difference between an experimental spectrum and a computed spectrum generated by summing the component curves. Generally, the procedure involves entering the values of the frequencies of the component bands (determined using derivatives and/or deconvolution) and then the program determines the best estimate of the parameters of the component curves. Apart from the obvious variables of peak height and width, the type of band shape needs to be considered. The class of band shape of an IR spectrum depends on the type of sample. A choice of Gaussian, Lorentzian or a combination of these band shapes is usually applied. Figure 25 illustrates the curve-fitting process.

### 4.2 Determination of Concentration

According to the Beer–Lambert law the absorbance of a solution is directly proportional to the thickness and the concentration of the sample (Equation 4):

\[
A = \varepsilon cl
\]

where \(A\) is the absorbance of the solution, \(c\) is the concentration and \(l\) the path length of the sample. The constant of proportionality is usually given the symbol \(\varepsilon\), and referred to as the molar absorptivity. The absorbance is equal to the difference between the logarithms of the intensity of the light entering the sample \((I_0)\) and the intensity of the light transmitted \((I)\) by the sample (Equation 5):

\[
A = \log_{10} \left( \frac{I_0}{I} \right)
\]

Absorbance is therefore dimensionless. Transmittance is defined by Equation (6) as:

\[
T = \frac{I}{I_0}
\]

The Beer–Lambert law tells us that a plot of absorbance against concentration should be linear with a gradient of \(\epsilon l\) and pass through the origin. In theory, to analyze a solution of unknown concentration, solutions of known concentration need to be prepared, a suitable peak chosen, the absorbance at this frequency measured, and a graph plotted (a calibration graph). The concentration of the compound in solution can be read, given that its absorbance is known.

However, there are a few factors which need to be considered first when taking this approach. When preparing the solutions of known concentration, the concentrations have to give sensible absorbance values – not too weak and not too intense. Choosing a suitable absorption peak is crucial. The technique should be as sensitive as possible so an intense peak should be chosen. However, often IR spectra have many, sometimes overlapping peaks. A peak isolated from others, with a high molar absorptivity is required. A further problem that sometimes arises, especially in the spectra of solid samples, is the presence of asymmetric bands. In these cases, peak height cannot be used because the baseline will vary from sample to sample. Peak area measurements should be used instead. Many FTIR spectrometers have accompanying software which can carry out these calculations. Quantitative measurements need to be carried out on absorbance spectra rather than on transmittance spectra. Thus, transmittance spectra need to be converted to absorbance spectra. Most spectrometers have this simple process incorporated into their software.
4.3 Simple Analysis

The quantitative analysis of a component in solution can be successfully carried out given that there is a suitable band in the spectrum of the component of interest. As discussed previously, the band chosen for analysis should: have a high molar absorptivity; not overlap with other peaks from other components in the mixture or solvent; be symmetrical; and give a linear calibration plot of absorbance versus concentration.

Most quantitative IR methods of analysis use the intensities of the C=O, N–H or O–H groups. The C=O stretching band is the most commonly used because it is a strong band in a spectral region relatively free of absorption by other functional groups. In addition, the carbonyl band is not as susceptible as the O–H and N–H bands to chemical change or hydrogen bonding.

Simple quantitative analysis may be illustrated using the example of aspirin dissolved in chloroform. The best peak to choose in this example is the C=O stretching band of aspirin observed at 1764 cm\(^{-1}\) because it is an intense peak and lies in a region where there is no interference from the chloroform spectrum. The next step is to draw a calibration plot of absorbance versus aspirin concentration. A series of chloroform solutions of known aspirin concentration were prepared and the IR spectrum of each solution was recorded using a 0.1 mm NaCl transmission cell. The intensity of the 1764 cm\(^{-1}\) band was measured for each solution and the results are listed in Table 5. This data can then be graphed to produce a linear plot, as shown in Figure 26. The next stage in the analysis is to determine the amount of aspirin present in a chloroform solution of unknown concentration. The IR spectrum of the unknown sample was recorded. The intensity of the 1764 cm\(^{-1}\) carbonyl band was measured and an absorbance of 0.351 was recorded. Examination of the calibration graph shows that this corresponds to a concentration of 67 mg mL\(^{-1}\).

IR spectroscopy can be used to measure the number of functional groups in a molecule, say the number of −OH or −NH\(_2\) groups. It has been found that the molar absorptivity of the bands corresponding to the group is proportional to the number of groups. That is, each group has its own intensity which does not vary drastically from molecule to molecule.

Solid mixtures can also be analyzed using IR spectroscopy. Solids are more susceptible to errors because of scattering. These analyses are usually carried out with KBr discs or in mulls. The problem here is the difficulty in measuring the path length. However, this measurement becomes unnecessary when an internal standard is used. Addition of a constant known amount of an internal standard is made to all samples and calibration standards. The calibration curve is obtained by plotting the ratio of the absorbance of the analyte to that of the internal standard, against the concentration of the analyte. The absorbance of the internal standard varies linearly with the sample thickness. The discs or mulls must be made under exactly the same conditions to avoid intensity changes or shifts in band positions. The standard must be carefully chosen and it should ideally have a simple spectrum with very few bands; be stable to heat and not absorb moisture; be easily reduced to a particle size less than the incident radiation without lattice deformation; be nontoxic, giving clear discs in a short time; and be readily available in the pure state. Some common standards used include calcium carbonate, sodium azide, naphthalene and lead thiocyanate.

4.4 Multicomponent Analysis

The analysis of a component in a complex mixture presents special problems. Quantitative analysis of a multicomponent system is illustrated by its application to

For caffeine:

\[
c = \frac{0.180}{[8.20 \times 10^{-2} \text{ mL mg}^{-1} \text{ mm}^{-1} \times 0.1 \text{ mm}]} = 22 \text{ mg mL}^{-1}
\] (12)

It should be pointed out that there could be a certain degree of error in these values. There can be error due to the fact that it is difficult to select a baseline for the analysis because of overlapping peaks. Also, any nonlinearity of the Beer–Lambert law plots has been ignored, having used one value to determine the constant of proportionality above for each solution.

Alternatively, this same problem can be determined by spectral subtraction. If a sample of the additive is available, mixtures of the starting material and product can be separated by subtraction of the spectra of the mixture and additives. This is achieved by subtracting the fraction of aspirin, then phenacetin and finally caffeine from the unknown sample spectrum to null the corresponding absorptions. The subtraction factors can be read from the spectrometer computer. This second method is, of course, much faster.

Studies of the trans unsaturation in fats also provide a good illustration of multicomponent analysis. Naturally occurring vegetable fats and oils are a mixture of triglycerides of the general structure shown in Figure 27. This is a tri-ester of glycerol. The acids are long chain and can be saturated or unsaturated. The unsaturation is always present as the cis isomer. These cis bonds can be isomerized to the trans configuration during extraction or subsequent processing. For example, oxidation or partial hydrogenation can lead to isomerization. It is commercially important for labeling to determine this trans content. It is difficult to separate cis from trans isomers using other techniques such as GC and an IR method is commonly used. The IR method has the convenience of no weighing being required, nor are any

\]

Figure 27 The molecular structure of triglycerides.
accurate volumes needed. It can therefore be used for very small samples.

The configuration of alkenes can be determined from the frequency of their C–H bending vibrations. Cis isomers absorb between 840 and 700 cm\(^{-1}\) while trans isomers absorb between 1000 and 930 cm\(^{-1}\). This band can be used as the basis for an analytical method. It is normal to hydrolyze the triglyceride mixture to glycerol and a mixture of fatty acids, and the latter then converted to their methyl esters. It is this methyl ester mixture which is analyzed. The formulae of methyl oleate, the cis isomer and methyl elaidate, the trans isomer, are given in Figure 28. Both geometrical isomers absorb strongly at 1163 cm\(^{-1}\), the C–O stretching frequency from the ester group. Cis isomers absorb weakly at 965 cm\(^{-1}\) while trans isomers absorb strongly at this frequency. It can be shown (Equation 13) that:

\[
\%\text{trans} = K \left( \frac{A_{965}}{A_{1163}} - f \right)
\]

where \(K\) and \(f\) are constants, and \(A_{965}\) and \(A_{1163}\) are the absorbances of the solution at these frequencies, respectively. Note that no concentration or path length terms appear in this equation. This is the equation of a straight line of gradient \(K\) and of \(y\)-intercept, \(f\), in a plot of \(\%\) trans versus the ratio of absorbances at the two frequencies, 965 and 1163 cm\(^{-1}\). A series of solutions of known trans composition are required, the ratio of absorbances then measured and the \(\%\) trans content is then plotted against these values.

The improvement in computer technology associated with spectroscopy has also led to the expansion of quantitative IR spectroscopy. The application of statistical methods to the analysis of experimental data is known as chemometrics. There is a large amount of information now available regarding chemometrics and a detailed discussion is beyond the scope of this article. However, there are several multivariate data analytical methods that are used for the analysis of FTIR data.\(^{11}\)

The most commonly used methods in IR spectroscopy are: classical least squares (CLS); inverse least squares (ILS); partial least squares (PLS); and principal component regression (PCR). CLS methods (also referred to as K-matrix methods by IR spectroscopists) use a calibration model representing the physical law that describes the variation in the spectra with composition. For example, the Beer–Lambert Law where absorbance is represented as a linear function of the component concentrations. ILS methods (also known as P-matrix methods) differ in that the data are empirically modeled without using a direct physical model. These calibration methods are not restricted to the use of the same number of components as the individual components present in the spectral region being analyzed. The newer PCR and PLS methods are two factor analysis based. Factor analysis methods are used to factor the spectral data matrix into the product of two small matrices in order to simplify the data representation. This allows a more stable solution to be achieved, compared to the use of the ILS approach.

5 APPLICATIONS

IR spectroscopy has been applied to quite a wide range of biological systems and a number of these are examined here. These include proteins, peptides, lipids, biomembranes, animal tissue, carbohydrates, pharmaceuticals, foods and plant material.

5.1 Proteins and Peptides

The IR spectra of proteins exhibit absorption bands associated with their characteristic amide group, the structural unit common to all molecules of this type (shown in Figure 29).\(^{12}\) An isolated planar amide group gives rise to five in-plane modes and one out-of-plane normal mode. The in-plane modes are due to C=O stretching, C–N stretching, N–H stretching, N–H bending, O–C–N bending, while the out-of-plane mode is due C–N torsion. Characteristic bands of the amide groups of protein chains are similar to absorption bands exhibited by secondary amides in general, and are labeled amide bands. There are nine such bands, called amide A, amide B and amide I–VII, in order of decreasing frequency and these bands are summarized in Table 8. Some of these bands are more useful for conformation

\[

\]

\[
\text{Figure 29 The amide group of proteins.}
\]
studies than others and the amide A, amide I and amide II bands have been the most frequently used. Knowledge of peptide bond vibrations is based mainly on normal coordinate calculations using N-methylacetamide as a model compound.

The most useful IR band for the analysis of the secondary structure of proteins in aqueous media is the amide I band, occurring between approximately 1700 and 1600 cm⁻¹. The amide I band represents (80%) C=O stretching vibration of the amide group coupled to the in-plane N–H bending and C–N stretching modes. The exact frequency of this vibration depends on the nature of hydrogen bonding involving the C=O and N–H groups and this is determined by the particular secondary structure adopted by the protein. Proteins generally contain a variety of domains containing polypeptide fragments in different conformations. As a consequence, the observed amide I band is usually a complex composite, consisting of a number of overlapping component bands representing helices, β-structure, turns and random structures.

The amide II band represents mainly (60%) N–H bending, with some C–N stretching (40%). Like the amide I band, it is possible to split the amide II band into components depending on the secondary structure of the protein. The position of the amide II band is sensitive to deuteration, shifting from around 1550 cm⁻¹ to a frequency of 1450 cm⁻¹. The amide II band of the deuterated protein overlaps with the H–O–D bending vibration, making it difficult to obtain information about the conformation of this band. However, the remainder of the amide II band at 1550 cm⁻¹ may provide information about the accessibility of solvent to the peptide backbone. Hydrophobic environments or tightly ordered structures, such as α-helix or β-sheet, reduce the chance of exchange of the amide N–H proton.

Secondary amides in the trans configuration exhibit two characteristic bands at about 3300 cm⁻¹ and 3100 cm⁻¹, while those in this configuration show two bands at about 3200 cm⁻¹ and 3100 cm⁻¹. The band at 3300–3200 cm⁻¹ is the amide A band and is due to the stretching mode of the N–H bond which is hydrogen bonded. The amide B is at 3100 cm⁻¹ and is due to the Fermi resonance of the N–H stretching vibration with the overtone of the amide II vibration for the trans configuration and with the combination of the C–O stretching and N–H in-plane bending vibrations for the cis configuration. The amide A and B bands are very sensitive to hydrogen bonding, but because of the mixed nature of these modes correlations between frequency shifts and hydrogen bonding are more complex than would be the case for an unperturbed N–H fundamental.

The amide III and the amide VII bands have not been studied as extensively as the amide A, B, I and II modes. The amide III and amide IV vibrations are complex in-plane modes with no more than about 40% of the potential energy associated with any single internal displacement coordinate. The amide IV and VII vibrations cannot even be said to be localized in the amide group and normal coordinate analysis of system containing several repeat units are necessary to interpret their relationship to structure.

Of the low frequency modes, the amide V vibration has been the most useful in structural investigations since it involves N–H out-of-plane bending and depends considerably on the backbone conformation. The amide V mode represents N–H out-of-plane bending and depends considerably on the backbone conformation. The band appears at around 600 cm⁻¹ for unordered structures and at around 650 cm⁻¹ for unordered structures and at around 700 cm⁻¹ for β-structure.

The amide IV, VI and VII modes have not yet been studied in detail and little information is available regarding their dependence on conformation. The amide IV band represents 40% O=C–H bending and 30% methyl–C stretching, the amide VI represents C=O out-of-plane bending. The amide VII band represents C–N torsion. Both of these modes have low intensities, making information difficult to obtain. Also, information is difficult to extract about the amide VII band because of its low frequency.

The amide III band is heavily mixed, representing 30% C–N stretching, 30% N–H in-plane bending and 20% methyl–C stretching. The amide III mode is also sensitive to secondary structure, but also gives rise to a very weak IR band at about 1300 cm⁻¹. Due to different selection rules, the amide VIII band is much stronger in the corresponding Raman technique, making Raman

spectroscopy a more suitable technique for studying this vibrational mode.

In general, a spectrum can only be properly analyzed if all the absorption bands are considered because there are no isolated vibrations involving only particular groups of atoms. However, for complex molecules it is possible to draw conclusions from the analyses of selected bands if the corresponding vibrations can be regarded as localized and this is true for many of the characteristic amide bands. It should be pointed out that the characteristic amide bands are not the only bands to appear in the spectra of proteins or simple model compounds. There are bands associated with C–H, C–N and C–C linkages in the spectra of model compounds.

In addition, the IR contributions of the side chains of the amino acids which constitute the protein must also be considered. Amino acid side chains exhibit IR modes that are often useful for investigating the local group in a protein. Fortunately these contributions have been found to be small in D₂O compared to the contributions made by the amide I band. It is also important to be aware of the location of such modes as they may be confused with amide vibrations. But the arginyl residue is the only residue which makes a significant contribution in the 1700–1600 cm⁻¹ region. However, even the bands at 1586 and 1608 cm⁻¹ due to the arginyl residue do not contribute greatly compared to the amide I contributions. The characteristic side chain IR frequencies of amino acids are summarized in Table 9.

Quantitative analysis of the secondary structures of polypeptides may be carried out. The amide I band of proteins and peptides consists of a series of overlapped component bands due to the secondary structures present in such molecules. Resolution enhancement of the amide I band allows the identification of various structures present in a protein or peptide. Derivatives and deconvolution can be used to obtain such information. Figure 30 illustrates the use of these methods to analyze the amide I mode of a peptide. However, simply measuring the peak heights of the resulting spectra does not provide an accurate measure of the proportion of secondary structure. In Fourier deconvolved spectra the band shapes are distorted and the extent of this distortion depends on the widths of the component bands and the parameters used to compute the deconvolved spectra, so the resulting peak heights are complex functions of a number of parameters. Similarly, the peak heights in the derivative spectra

The amide I band frequencies and secondary structure assignments cannot be used as a quantitative measure because they are functions of both intensities and the widths of the original bands. The best method used for the estimation of protein secondary structure involves band-fitting the amide I band. The parameters required, the number of component bands and their positions, are obtained from the resolution enhanced spectra. The fractional areas of the fitted component bands are directly proportional to the relative proportions of structure that they represent. The percentages of helix, \(\beta\)-structure and turns are estimated by addition of the areas of all the component bands assigned to each of these structures and expressing the sum as a fraction of the total amide I area. The assumption is made that the intrinsic absorptivities of the amide I bands corresponding to different structures are identical.

IR spectroscopy has been used in a large number of studies of proteins in a range of environments. Some examples of the proteins analyzed are listed in Table 10, which details the deconvolved amide I frequencies and secondary structure assignments made for a series of proteins in D\(_2\)O.\(^{(14)}\) These assignments are based on the fact that the secondary structures of these globular proteins have been very well characterized by X-ray crystallography. The characteristic frequencies of the secondary structures of proteins have also been estimated from normal coordinate calculations on model peptides and proteins of known structure.\(^{(13)}\) The frequencies are summarized in Table 11. These assignments are by no means exact and some bands may appear outside these ranges for some proteins, particularly when solvent interactions are considered.

An example of the quantitative approach to protein analysis is illustrated by Figure 31 which shows the amide I band of the enzyme lysozyme in D\(_2\)O. The amide I band of this protein shows nine component bands and the relative frequencies of these bands are summarized in Table 11.
areas of these components are listed in Table 12. The components may be assigned to the various types of secondary structures. The bands at 1623 and 1632 cm\(^{-1}\) are characteristic of \(\beta\)-structure, as is the band at 1675 cm\(^{-1}\). The bands at 1667, 1684 and 1693 cm\(^{-1}\) occur at frequencies characteristic of turns and bends. The band at 1610 cm\(^{-1}\) is due to arginyl side chain vibrations and the 1640 cm\(^{-1}\) band may be assigned to random coil. The two remaining bands at 1648 and 1657 cm\(^{-1}\) are due to the presence of \(\alpha\)-helix. Usually in protein IR spectra only one component due to \(\alpha\)-helix is observed. However, X-ray data indicates the presence of two types of helix in lysozyme: \(\alpha\)-helix and 3-turn helix. These different helices vibrate at different frequencies. The 1657 cm\(^{-1}\) is assigned to \(\alpha\)-helix, while the 1648 cm\(^{-1}\) band is due to 3-turn helix. These assignments give a quantitative estimate of 48% helix, 23% \(\beta\)-structure, 13% turns and 16% random coil in lysozyme.

Peptides are often derived from the larger proteins, and a similar quantitative approach can be applied to these molecules. However, their small size must be taken into account when applying such methods. Small peptides are not necessarily capable of producing the same secondary structures observed in proteins. The CiT4 peptide is derived from a nervous system protein and consists of a sequence of 26 amino acids. The amide I band of CiT4 peptide in D\(_2\)O has been deconvolved and curve-fit and the results are illustrated in Figure 32. Table 13 lists the wavenumber and the fractional area of each component of the amide I band of CiT4 in D\(_2\)O. The major component in Figure 32 is observed at 1644 cm\(^{-1}\), contributing to 73% of the total amide I band area. This frequency is characteristic of random coil in proteins and peptides. Two smaller component bands appear at 1664 and 1674 cm\(^{-1}\), respectively, and both can be attributed to turns and bends in the peptide structure. The weak component at 1617 cm\(^{-1}\) is at a frequency associated with arginine side chain contributions.

The solvent environment in which proteins and peptides are recorded affects the secondary structures observed for these molecules. For instance, the solvent trifluoroethanol (TFE) is more polar than water. The FTIR spectrum of the CiT4 peptide in TFE/D\(_2\)O is shown in Figure 33. The frequency and the fractional area of

each component of the amide I band of CiT4 in TFE solution are listed in Table 14. There are significant changes observed to the amide I band of CiT4 in the presence of TFE. There is a notable change in the shape of the amide I band and six component bands are observed. The small component at 1610 cm$^{-1}$ occurs in the frequency range normally attributed to side chain contributions. The components at 1623 and 1637 cm$^{-1}$ are assigned to low-frequency $\beta$-structure, with a high-frequency component of $\beta$-structure also observed at 1675 cm$^{-1}$. These bands contribute to 43% of the total band area. The component in Figure 33 observed at 1655 cm$^{-1}$, contributing to 21% to the total amide I band area, is assigned to $\alpha$-helix. The remainder of the components in Figure 33 at 1661 and 1689 cm$^{-1}$ are assigned to turns and bends in the peptide secondary structure. Analysis of the spectrum of CiT4 in TFE/D$_2$O solution indicates differences in the secondary structure of the peptide when compared to that observed for the peptide in the pure aqueous solution. On addition of TFE, a more structured conformation of CiT4 is indicated. Notably $\alpha$-helical structure and $\beta$-structure appear to be formed in the less polar environment provided by TFE. Thus, a change in environment, in this case solvent, can cause notable changes to a peptide conformation observable using IR spectroscopy.

IR techniques can also be used to study protein adsorption onto surfaces. For example, a flow-through ATR cell can be used ex vivo with flowing blood. Blood–surface interactions are of great importance when medical polymers, such as those used in heart valves and artificial organs, are implanted into the body. When polymers come into contact with blood, complex reactions take place and can result in the formation of a blood clot. IR analysis has shown in ex vivo studies of dogs that during the early stages the proteins albumin and glycoprotein are present. Immediately after this observation increased amount of fibrinogen appear. As the adsorption process continues, albumin is replaced by other proteins until a blood clot is formed.

5.2 Lipids

Many of the lipids found in nature contain phosphorus and are classed as phospholipids. One class of phospholipid are the phosphoglycerides and the general structure of this type of lipid is illustrated in Figure 34. Phospholipids are organized in lipid bilayers of about 40–80 Å in thickness, where the polar head group points towards the aqueous phase and hydrophobic tails point towards the tails of a second layer. The chains can be in an all trans conformation which is referred to as the gel phase. A liquid crystalline phase is obtained when the chain also contains gauche C–C groups.

The IR spectra of phospholipids can be divided into spectral regions which originate from molecular vibrations of the hydrocarbon tail, the interface region and the head-group. The major IR modes due to phospholipids are summarized in Table 15. The hydrocarbon tail gives rise to acyl chain modes. The most intense vibrations in the IR spectra of lipid systems are the CH$_2$ stretching vibrations. These give rise to bands in the region 3100 to 2800 cm$^{-1}$. The CH$_2$ asymmetric and symmetric stretching modes at 2920 and 2851 cm$^{-1}$, respectively, are generally the strongest bands in the lipid spectra. The frequencies of these bands are conformation-sensitive and respond to changes of the trans/gauche ratio in the acyl chains. This is also the case for the vibrational modes due to the terminal CH$_3$ groups at 2956 cm$^{-1}$ (asymmetric stretching) and 2873 cm$^{-1}$ (symmetric stretching). The C=C–H stretching bands due to unsaturated acyl chains are found at 3012 cm$^{-1}$. The bands due to methylene and methyl groups occur in the 1500–1350 cm$^{-1}$ region. At around 1470 cm$^{-1}$ there are bands due to CH$_2$ bending and the number and frequency of these bands are dependent on acyl chain packing and conformation. While the asymmetric

Deformation modes of the CH3 group are obscured by the scissoring bands, the symmetric deformation mode appears at 1378 cm⁻¹. The polymethylene chains show a series of bands in the region 1380–1180 cm⁻¹ but these are obscured in the spectra of phospholipids because they overlap with the strong PO2⁻ asymmetric stretching band around 1228 cm⁻¹. There is also a series of CH2 rocking bands in the 1150–700 cm⁻¹ region. The most intense band of this group is at 720 cm⁻¹ and overlaps with a strong H2O band, so it is necessary to observe it in D2O. Deuteration of lipids result in C−D stretching frequencies in the 2000–2300 cm⁻¹ region, a region free from interfering absorption bands. As for the C−H stretching bands, the C−D stretching bands are sensitive to the conformation and the trans/gauche ratio of the deuterated acyl chain segments. Bands around 2195 and 2090 cm⁻¹ are due to the CD2 asymmetric and symmetric stretching vibrations, respectively. Bands at 2212, 2169 and 2070 cm⁻¹ arise from the CD3 group. Deuteration also simplifies the fingerprint region of the IR spectra as the methylene wagging and rockimg-twisting band progressions disappear from their usual position in the 1400–700 cm⁻¹.

Spectral modes arising from the head-group and interfacial region also provide useful information. The most useful IR bands for studying the interfacial region of lipid assemblies are the ester group vibrations, particularly the C=O stretching bands in the 1750–1700 cm⁻¹ region. In diacyl lipids this region consists of at least two bands originating from the two ester carbonyl groups. A band at 1742 cm⁻¹ is assigned to the C=O mode of the sn-1 chain with a trans conformation in the carbon–carbon bond adjacent to the ester grouping, while the 1728 cm⁻¹ C=O frequency of the sn-2 chain suggests the presence of a gauche band in that position. The frequency difference observed reflects the structural inequivalence of the chains, with the sn-1 chain initially extending in a direction perpendicular to the sn-2 chain and then developing a gauche bend in order to render the two chains parallel. For example, the C=O stretching region of the spectrum of the lipid phosphatidylserine (PS) is shown in Figure 35. The band at 1624 cm⁻¹ is due to the asymmetrical CO2⁻ stretching vibration of PS. The band at 1737 cm⁻¹ is broad, consisting of two ester C=O stretching bands at 1742 and 1728 cm⁻¹ and a small band at 1701 cm⁻¹ which is assigned to a hydrogen-bonded carbonyl group. The higher frequency band at 1742 cm⁻¹, associated with the sn-1 chain of PS is the more intense band, indicating that a trans conformation of the chain about the C−C bond is favored.

The choline, ethanolamine and serine groups have characteristic modes. The CH3 asymmetric stretching modes of the (CH3)2N¹ group are around 3040 cm⁻¹ and are out of the range of the acyl chain CH3 bands. The corresponding methyl bending vibrations of the choline group occur at higher frequencies, compared to those of the acyl chain methyl groups. The C−N stretching bands are found between 1040 and 800 cm⁻¹. There are also several characteristic phosphate group vibrations. There are strong bands due to the P=O stretching vibration: an asymmetric PO2⁻ stretch around 1228 cm⁻¹ and a symmetric PO2⁻ stretch around 1085 cm⁻¹. There are P−O stretching modes in the region 900–800 cm⁻¹, but these are obscured by strong water absorption in this region.

In certain phospholipid membranes which contain unsaturated acyl chains, the typical lamellar liquid crystalline phase converts to a micellar nonlamellar phase.

Figure 35 The C=O stretching region of PS in D2O.
Figure 36: The temperature dependence of the symmetric CH$_2$ stretching band of PE.

Upon heating, such a thermally-induced transition involves a major structural rearrangement. Temperature studies of the IR spectra of phospholipids provide a sensitive means of studying such transitions in lipids. Figure 36 shows the temperature dependence of the frequency of the symmetric CH$_2$ stretching band in the spectra of lipid membranes obtained from phosphatidylethanolamine (PE). The increasing frequency with temperature indicates an increasing concentration of gauche bands in the acyl chains and this leads to the formation of the nonbilayer phase at higher temperatures. Figure 36 shows a frequency shift of about 2 cm$^{-1}$ at 18°C and this is associated with the gel to liquid crystal phase transition. An additional frequency shift of approximately 1 cm$^{-1}$ at 50°C is associated with a transition to the micellar phase. Both these transitions have been observed to be reversible.

Quantitative IR analysis can be carried out on blood serum to determine the relative amounts of lipid present. Triglycerides, phospholipids and cholesteryl esters are the classes of lipid which occur in blood serum. These compounds occur naturally in concentrations which make IR analysis attractive, and the necessary preliminary separation is simple. These classes of compounds can be characterized using IR spectroscopy by their carbonyl bands. The peak maxima are:

- triglyceride 1742 cm$^{-1}$
- phospholipid 1737 cm$^{-1}$
- cholesteryl ester 1723 cm$^{-1}$.

However, the carbonyl peaks are heavily overlapped and these are too close to allow analysis by three simultaneous equations, but a least-squares method can be used to separate the components. The concentrations of these lipid components are usually in the range 0.03–0.3% in human blood, and standard solutions can be prepared in chloroform.

5.3 Biomembranes

FTIR spectroscopy is particularly useful for probing the structure of membrane proteins. Until recently a lack of adequate experimental techniques has been the reason for the poor understanding of the secondary structure of most membrane proteins. X-ray diffraction requires high quality crystals and these are not available for many membrane proteins. Circular dichroism (CD) has been widely used for studying the conformation of water-soluble proteins, but problems arise for its use for membrane proteins. The light scattering effect may distort CD spectra and lead to substantial errors in their interpretation. Also, the reference spectra used for the analysis of CD spectra are based on globular proteins in aqueous solution and may not be applicable to membrane proteins in the hydrophobic environment of lipid bilayers. IR spectroscopy is largely unaffected by the aforementioned problems. The technique can be used to study the secondary structure of proteins both in their native environment, as well as after reconstitution into model membranes. IR spectroscopy offers several advantages for studies of protein–lipid interaction. Information about lipid conformation and protein secondary structure from the same sample can be obtained in a single experiment.

Myelin basic protein (MBP) is a major protein of the nervous system and has been studied using FTIR spectroscopy in both aqueous solution and after reconstitution in myelin lipids. The amide I band of MBP in D$_2$O solution (deconvolved and curve-fit) illustrated in Figure 37. The amide band shows a small band at 1616 cm$^{-1}$ which occurs at a frequency normally attributed to amino acid side chain contributions. The largest component band observed at 1647 cm$^{-1}$ is assigned to random coil and accounts for 86% of the total band area. The remaining component band at 1671 cm$^{-1}$ is assigned to turns and bends in the protein. Table 16 lists the frequency and the fractional area of each component of the amide I band of MBP in D$_2$O. The FTIR spectrum of MBP protein after reconstitution in myelin with all proteins removed was also recorded. The results of deconvolution and band-fitting the amide I band of MBP in myelin are shown in Figure 38. The frequency and the fractional area of each component of the amide I band of MBP in myelin are listed in Table 17.

observed to the amide I band of MBP when the protein is complexed with myelin. In Figure 38 the two small components at 1606 and 1616 cm$^{-1}$ occur in the frequency range attributed to side chain contributions. The appearance of the band at 1624 cm$^{-1}$ indicates the presence of water-bonded $\beta$-structure. Also, the component at 1634 cm$^{-1}$ is assigned to $\beta$-structure, with a high-frequency component due to $\beta$-structure observed at 1675 cm$^{-1}$. These bands contribute to 40% of the total band area. This estimation indicates that a notable amount of $\beta$-structure is formed when the results are compared to those obtained for MBP in D$_2$O where no $\beta$-structure was observed. The component at 1651 cm$^{-1}$, contributing to 28% of the total amide I band area, is assigned to $\alpha$-helix in the protein. Thus, reconstitution of MBP in myelin produces a significant amount of $\alpha$-helix in the protein in the predominantly lipid environment. Again, none of this type of structure was observed for the protein in an aqueous environment. The small component at 1642 cm$^{-1}$ appears at a frequency normally attributed to random coil. The remainder of the components in Figure 38 at 1663 and 1686 cm$^{-1}$ are assigned to turns and bends in the protein. Thus, the importance of the conditions in which biological molecules are examined in the IR needs to be emphasized. It is observed here with the example of MBP that the protein is very sensitive to the surroundings. The latter lipid environment more closely mimics the native environment, and thus presumably gives a far better indication of the native structure.

5.4 Animal Tissue

In recent years IR spectroscopy has been used in clinical analysis.\textsuperscript{20,21} In particular, high-pressure (pressure-tuning) IR spectroscopy has been developed as a successful technique for the evaluation of malignancy in human tissues. The pressure dependence on parameters such as frequency, intensity and band shape can provide further information about the structural changes associated with malignancy. For example, it is possible to detect cervical cancer arising from a premalignant state termed dysplasia by using IR band differences among normal, dysplastic and malignant cervical cells. A study of the pressure dependence of the frequencies of bands indicates that there are extensive changes in the degree of hydrogen bonding of phosphodiester groups of nucleic acids and the C=O groups of proteins. Pressure studies also indicate changes in the degree of disorder of methylene chains of lipids in the malignant tissue. The IR spectra of tissue...
samples with dysplasia demonstrate the same changes to a lesser degree than those observed for the cancer samples. Figure 39 shows the pressure dependence of the CH₂ bending mode frequency of the methylene chain of lipids for both normal and malignant tissue. Pressure increases this frequency because it induces ordering of the methylene chains in the lipid bilayers, thus increasing interchain interactions. In malignant cervical tissue, pressure induces a smaller shift in the frequency of this mode compared with normal tissue. The difference indicates that in cervical cancer the methylene chains of lipids are more disordered than in normal cervical tissue.

Skin samples are often used to study the interactions of various chemical mixtures, such as lotions, with living tissue. FTIR microscopy offers a valuable tool for these types of analyses as living skin is relatively expensive and difficult to obtain. This technique has been used to study a piece of living skin treated with a conditioning emollient. The sample was then subjected to various washes. Figure 40 shows the FTIR microscopic spectrum of the skin (200 × 200µm) after treatment with the emollient followed by washing. Figure 40 also shows the spectrum of a piece of control skin. Comparison of the spectra indicates the appearance of a band near 730 cm⁻¹ due to the long chain aliphatic hydrocarbon component of one of the lotions constituents. Also, there is the notable appearance of a band at 1040 cm⁻¹ due to hydroxy C–O stretching related to one of the active ingredients in the emollient. This example demonstrates how an IR microscope can be utilized as a probe for measuring the presence of chemicals on skin.

5.5 Carbohydrates

The structure of monosaccharides has been successfully studied using IR spectroscopy. For example, IR spectroscopy can be used to clarify the structure of the simple sugar glucose. Although glucose exists almost entirely in the cyclic form, in solution it appears to be in equilibrium with a minute amount of the noncyclic form. Figure 41 shows these glucose structures. IR spectroscopy has been used to show that the acyclic form of this sugar is not present to any appreciable extent because it equilibrates to give different cyclic forms. The acyclic form of the glucose has an aldehyde group present and should
of drugs, excipients and the raw materials used in the manufacture of pharmaceuticals. FTIR spectroscopy has been used to differentiate the structures of penicillins. The general structure of penicillins is shown in Figure 44, where the R group depends on the nature of the particular penicillin. Table 19 lists the major characteristic IR bands of penicillins recorded in D₂O. Quantitative analysis can be readily performed using the intensity of the β-lactam carbonyl stretching band.

GC/IR is an appropriate technique for drug analysis as it can be used for isomer separation or contaminant detection. The technique is emerging as a complementary method to GC/MS, which is generally accepted as the most definitive method for identification of drugs of abuse in urine, for instance. Amphetamines are one class of drug

which have been successfully differentiated using GC/IR. Amphetamines are structurally similar molecules which can be easily misidentified. In particular, there are some common ‘designer drug’ derivatives of amphetamine. However, although such similar compounds cannot be differentiated by their mass spectra, there are prominent differences in their IR spectra. Figure 45 illustrates the FTIR spectrum of an amphetamine derivative detected using GC/IR.

5.7 Foods

Near-IR spectroscopy has proved to be a very useful technique for the investigation of foods.\(^{25}\) The major IR modes in this region in the spectra of foods are due to O–H, N–H and C–H groups. These groups appear due to the presence of proteins, carbohydrates and fats in food. Near-IR has been used in a wide range of studies in food analysis, including the protein content of wheat and meat, analysis of fiber, and oil in mayonnaise. Figure 46 shows the near-IR spectrum of dehydrated tomato soup and this illustrates the modes of common food components.

Wine analysis is also feasible with near-IR spectroscopy. Near-IR provides a relatively straightforward method of analyzing ethanol in wine. The O–H bond in ethanol produces a near-IR mode that is easily distinguished from the O–H mode of water. In the 1980s the wine industry was troubled by several cases of adulteration using diethylene glycol and methanol. Methanol is easily distinguished from ethanol in the near-IR. Figure 47 illustrates that a 1% addition of methanol to a wine sample is easily distinguished from a 1% addition of ethanol. Thus, near-IR spectroscopy has potential as a method for the routine screening of wine.

Near-IR is also an effective approach to the analysis of artificial sweeteners. The near-IR spectrum of saccharin is shown in Figure 48. As aromatic compounds are not very common in food products so modes due to those compounds are useful. Although saccharin is found at low concentrations in foods, it is normally added as a concentrated solution and this can be monitored by near-IR measurements in the presence of other ingredients.

5.8 Plant Material

FTIR spectroscopy has emerged as a suitable tool for the investigation of plant material.\(^{7}\) For instance,
it can be used to examine the quality of animal food, such as alfalfa. There is a relationship between the quality of alfalfa as a food supplement and the plant age. IR microscopy can be used to compare an old plant with a young plant. Figure 49 shows the spectra of an old and young leaf (both 100 × 100 μm). At first sight it is difficult to discern any major differences between these spectra. However, spectral subtraction illustrates some important differences. Figure 50 shows the difference spectrum obtained by subtracting the spectrum of the young plant from that of the older plant. Positive bands indicate a higher relative concentration in the older leaf and negative bands indicate a high concentration in the younger plant. A higher protein content in the young plant is suggested by the negative amide I and amide II bands at 1650 and 1545 cm⁻¹, respectively. Thus, Figure 50 tells us that there is a significant difference in the cellulosic nature of the two samples, with the older plant having a higher relative cellulose content.

Mass spectrometric methods may serve as powerful analytical methods in life sciences and medicine. Mass spectrometry (MS) is comparable in sensitivity to techniques based on chromatography or electrophoresis but has superior resolution. Although there are a number of suitable ionization methods, allowing the analysis of biological molecules that are of high molecular weight and low volatility, there are mainly two "soft-ionization" techniques that confer only a minimum of degradation of the analyte: MALDI (matrix-assisted laser desorption/ionization) and ESI (electrospray ionization).

The following article provides a short overview on the advantages and drawbacks of MALDI analysis of biological samples. Whereas most applications of MALDI are in the field of protein analysis, the analyses of carbohydrates and lipids are also comprehensively discussed. It is shown that MALDI is a useful tool especially in the field of lipid analysis, whereas with carbohydrate analysis, still a number of problems have to be solved. MALDI is a rapid and very sensitive (from the low picomolar to the attomolar range) tool that tolerates high amounts of impurities (in contrast to ESI), which are typically present in biological samples. A further advantage is that mainly singly charged ions are formed; this enables MALDI to be applied even to the analysis of crude mixtures although ion yields may differ significantly in dependence on the molecules of interest. In comparison with ESI, MALDI detects compounds of higher molecular weights more sensitively, whereas ESI is more suitable for labile compounds. Therefore, the combination of both methods is, in many cases, the ideal solution for a number of analytical problems.

1 INTRODUCTION

Chemists and biochemists were searching for a long time for a simple method to accurately and sensitively determine the molecular masses of naturally occurring biopolymers such as proteins or polysaccharides. Established methods in this field today are chromatographic techniques (gel filtration) or gel electrophoresis (sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE)). However, both methods are relatively time-consuming and do not provide high mass accuracy.\(^{(1)}\)
MS is superior to all other techniques for mass resolution. Highlights in the development of MS, showing its unusual high mass resolution, are the exact determination of atomic weights and the discovery of new isotopes of a given element. The main problem in MS, however, is that the sample has to be evaporated to form intact, isolated, ionized molecules in the gas phase.

Unfortunately, because of their high polarity and often extremely high molecular weight (and the resulting low volatility), most biopolymers cannot be ionized by the “classical” electron impact (EI) mass spectroscopy method,\(^2\) which is widely used for the analysis of small molecules with molecular weights up to about 1000 Da.\(^3\)

In this approach, most information is obtained from typical fragmentation patterns and the intensity of the molecular ion is often very weak or is even completely absent for biopolymers.

Since the mid-1970s, new volatilization and ionization techniques that also allow the analysis of high-molecular-weight polar biopolymers have been developed. Although mass spectrometers were already being manufactured during or just after World War II by several companies, some time passed until the EI technique was extended with the invention of the field ionization (FI) and field desorption (FD) techniques in which the sample was ionized by a strong electric field gradient, resulting in less fragmentation.\(^4\)

Although the molecular masses of polymers that could be analyzed by this technique were rather low, this was the initial step toward making MS also suitable for biological samples. At much the same time, the potential of the technique of chemical ionization (CI) (discovered by Thompson in 1913) was recognized. In this approach, the analyte is ionized through its reaction with gas molecules (e.g. ammonia).\(^5\) This technique is much more gentle than EI and generates less fragment ions, allowing the determination of the molecular weight by the detection of the molecular ion. Secondary ion mass spectrometry (SIMS),\(^6\) plasma desorption (PD) mass spectrometry,\(^7\) and laser desorption (LD) mass spectrometry\(^8\) soon followed. Fast atom bombardment (FAB) is very successful for the analysis of highly polar, low-volatility compounds but has the disadvantage of producing a large amount of fragmentation.\(^9\) An overview of the most important ionization techniques, their benefits, and drawbacks is given in Table 1.

Two rather new “soft-ionization” techniques\(^9\) (i.e. with only a very small amount of fragmentation) are ESI\(^2,10\) and MALDI\(^1\) which now are successful MS methods since both are suitable for the analysis of large biopolymers. A further advantage is the rather simple and less-expensive experimental design allowing simple time-of-flight (TOF) instruments to be used.\(^5\) Therefore, compared to classical instruments, such modern mass spectrometers are rather small.

In 2002, the inventors of these techniques, Tanaka et al.\(^12\) and Fenn et al.\(^13\) were awarded the Nobel Prize for the development of MALDI and ESI, respectively.\(^14\) It should be noted that in the very first “MALDI” study, ultrafine cobalt powder was used as the “matrix”.\(^12\)

Nowadays, however, organic matrix compounds are nearly exclusively used for many different reasons. The latter approach was developed by Franz Hillenkamp and Michael Karas in Germany and was published already in 1988.\(^15\)

Although ESI and MALDI yield comparable (often complementary) information, this article mainly deals with the application of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOF MS) for the analysis of biologically relevant samples. MALDI/TOF is primarily established in the field of protein\(^16–18\) and peptide analysis.\(^19\)

Terms such as “proteomics”\(^20\) or even “peptidomics”\(^21\) are nowadays widely established, although their exact definition still remains to be specified. Nevertheless, its applicability for carbohydrate\(^22,23\) and lipid analysis\(^24,25\) is also described and compared with other MS methods.

### 1.1 What is Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

A comprehensive description and the theoretical basics of classical MS and the corresponding experimental equipment are discussed in detail in other articles in this Encyclopedia. Here, only a few comments on the special features of MALDI/TOF MS are given. This is one of the fastest and most accurate methods to determine a number of polymer (mainly biopolymers) characteristics, especially their molecular weight and the corresponding weight distribution.\(^16\)

MALDI is based (in most cases) on the utilization of a matrix that absorbs ultraviolet (UV) light. Although lasers with other emission characteristics (e.g. in the infrared (IR) range) are also available today, the focus is still on UV lasers because they are nearly exclusively available on commercial mass spectrometers. The use of an appropriate matrix was independently introduced in 1988 by Hillenkamp and Karas\(^15\) and Tanaka et al.\(^12\) The technique has become an established tool in biochemical analysis, and the number of publications on the principles and applications of MALDI for biological problems is constantly growing (Figure 1).

There has been a tremendous increase in the number of publications dealing with this topic and it is nearly impossible to open a recent issue of a journal such as *Analytical Chemistry* or *Analytical Biochemistry* without finding at least one paper on MALDI/TOF MS. It is also evident from Figure 1 that there are less papers dealing

GC/MS, gas chromatography/mass spectrometry.

with MALDI (white bars) than with ESI (black bars). The reader should note that this is not due to the lower importance of MALDI but due to the fact that ESI is also applicable to very small molecules as no matrix is used. Such molecules are difficult to analyze by MALDI only because of the significant contribution of matrix peaks in this mass region. This topic has been recently reviewed, for instance, in the excellent book by Hillenkamp and Peter-Katalinić.\(^{(26)}\)

The most important observation for the development of MALDI was the minimal degree of fragmentation (in comparison with other MS techniques like LD) of the analyte achieved by using a suitable matrix compound. The matrix has two important tasks: to absorb the laser energy and to separate the analyte molecules from each other to avoid cluster formation. Therefore, the matrix and the sample are mixed in an appropriate solvent with an approximately 1000–10000-fold molar excess of the matrix. The main requirements of a “good” matrix are its absorption properties at the laser wavelength used, the low extent of fragment ion formation, and good mixing properties with the analyte to give homogeneous crystallization.\(^{(27)}\) Finally, the yield of matrix peaks should be very moderate, particularly if the analysis of small molecules is planned.\(^{(26)}\) The sample–matrix mixture is subsequently placed onto a special sample probe tip (because it is irradiated by the laser, it is often called the target), which, for most instruments, allows the investigation of a number of samples. The required amount of sample is normally in the
Figure 1  Number of scientific papers containing in their abstract the terms “MALDI” or “matrix-assisted” (white bars) or “ESI” or “electrospray” (black bars) and the respective year of their publication. Data were taken from the “Web of Science” database.

Figure 2  Typical sample plate (Voyager) for MALDI/TOF analysis comprising a 10 × 10 matrix of 1-µL wells etched into the stainless steel with gold cover. The dimensions of the plate are 57 × 57 mm and the individual wells are 2.54 mm in diameter.

A description of the processes occurring at the sample in the mass spectrometer is given in Figure 3.
Figure 3  Schematic representation of events occurring in a conventional MALDI/TOF mass spectrometer. The analyte–matrix mixture is evaporated and ionized by laser irradiation. These ions are accelerated in an electric field and then allowed to drift in a field-free pathway. Over this distance, a separation between low-mass and high-mass ions occurs. The “time-of-flight” \( t \) depends on the flight path \( L \), the mass of the ion \( m \), its energy \( eU \), and the number of charges \( z \). (Figure was published in ref. 25, © Elsevier 2004.)

When the pulsed laser beam (we focus exclusively on \( \text{N}_2 \) lasers emitting at 337 nm) hits the probe, the laser energy is transferred to the UV-absorbing matrix, which is partially vaporized and carries intact analyte molecules into the vapor phase. In this expanding gas cloud, all ions ablated from the sample plate have nearly the same velocity of about 500 m s\(^{-1}\) and a half-width distribution of approximately 100 m s\(^{-1}\) (strongly dependent on the used matrix).\(^{16}\) During the expansion of this gas cloud, protons and ions like Na\(^+\) are exchanged between the analyte (often a protein, but lipids, many carbohydrates, deoxy ribonucleic acid (DNA), and artificial polymers can be analyzed in the same way) and the matrix molecules, leading to the formation of positively and negatively charged analyte molecules. Unfortunately, despite its importance for MALDI, the process of ion formation is only poorly understood so far, and further physical and chemical investigations are absolutely required.\(^{11,33}\)

However, an important difference between MALDI and the classic ionization techniques is that MALDI provides pulsed ion generation and not continuous ion formation. Requirements for the properties of the laser are stringent: to avoid thermal decomposition of the thermally labile molecules, the energy must be transferred within a very short time. Typical laser pulse widths are in the range 1–100 ns.\(^{16}\)

Once formed, the ions are accelerated in a strong electric field, with typical accelerating voltages of approximately 20 kV. After passing a charged grid, the molecules drift freely over a field-free space, which is, for most MALDI/TOF spectrometers, in the range of 0.50–3 m. The length of this field-free TOF pathway influences the achievable mass resolution: ions of low mass arrive at the detector faster than do those of higher mass; consequently, ions of different masses can be separated. An appropriate recorder at the end of the flight tube produces a signal upon the impact of each ion group.\(^{16}\) The TOF spectrum is a simple recording of the detector signal as a function of time. The relationship of time \( t \) with the square root of the mass-to-charge ratio \( m/z \)\(^{1/2}\) is used to calculate the ion mass from the measured TOF, from which a conventional mass spectrum (intensity over the \( m/z \) ratio) is obtained. It must be emphasized that the ionization process does not only form positively charged ions.\(^{11}\) Some molecules, especially acidic molecules carrying negatively charged groups, are more easily detected as negative ions than as positive ions. Switching from the detection of positive ions to the observation of negative ions is simply performed by inverting the polarity of the accelerating field.

Although a comprehensive theoretical treatment is outside the scope of this review, a few comments on the parameters influencing the mass resolution of MALDI/TOF mass spectrometers are necessary. Mass resolution \( (m/\Delta m) \) is a measure of a spectrometer’s capability to produce separate signals from ions of similar mass. From the equation given in Figure 3, it is evident that the length of the TOF path \( L \) influences the mass resolution since the separation of the individual ions occurs over this distance. Therefore, resolution can be enhanced using longer flight tubes. However, to construct the small spectrometers with relatively short flight tubes that are preferred, a certain trick is used: ions are reflected at the end of the flight path by a so-called electrostatic mirror and reach the “reflector detector” at the opposite end.\(^{10}\) A schematic comparison between the linear mode and the reflector mode is given in Figure 4.
Most modern mass spectrometers can be operated in both ways. Unfortunately, the gain of mass resolution in the reflector mode is accompanied by a loss of sensitivity since the total number of ions is spread over a wider range. Mass resolution obtained with common MALDI/TOF spectrometers is relatively poor in comparison with other MS methods, since ions exhibit a broad kinetic energy distribution that is largely a result of the initial velocity imparted to the ions during the desorption/ionization process. This leads to considerably broadened peaks in the mass spectrum. To minimize the influence of the initial velocity of the ions, modern MALDI/TOF spectrometers can be run in a special “delayed extraction” (DE) mode, where the velocity distribution of formed ions is minimized and, therefore, the mass resolution is enhanced. In short, a gradient field, not a constant electric field, is used for the acceleration of the ions. This field is high close to the ion source and decreases with the distance. Accordingly, the faster ions experience a weaker field, whereas the slower ions experience a stronger field. If the parameters are carefully adjusted, all ions with the same m/z value arrive at the detector at the same time and peak broadening effects can be avoided. This technique is also termed time-lag energy focusing.\(^{(34)}\)

Further information on this technique, which is now available on many mass spectrometers, can be found in some further reports.\(^{(16,34)}\) The spectra of compounds with a relatively low molecular weight (up to 4 kDa) that are shown below were recorded with DE.

Of course, the determination of the molecular weight alone does not provide structural information and tandem mass spectrometry (MS/MS) is often required. Tandem mass spectrometry is the process of selecting an ion, causing it to fragment and obtaining a mass spectrum of the resulting fragment ions. Although MALDI devices with real MS/MS are nowadays commercially available, they are seldom used, as they are expensive. However, if MALDI-TOF devices with a reflectron are available, it is possible to record “post source decay” (PSD) spectra that may also be helpful to obtain some structural information on the compound of interest: A given parent ion penetrates to the back of the reflectron and may be easily focused onto the detector. Fragment ions of the parent ion do not penetrate as deeply and consequently, are not as well focused. This problem can be overcome by acquiring several spectra (known as segments) at reduced reflectron voltages. The different mass regions are then stitched together to form a single “PSD” spectrum representing principally an MS/MS spectrum. This “PSD” must be clearly differentiated from “in source decay” that occurs directly in the ion source and primarily contributes massively to the “chemical spectral noise”.

TOF/TOF instruments may be additionally combined with “collision-induced dissociation” (CID): an inert gas (Ar or He at a certain pressure is commonly used) is introduced into a special collision cell between both TOF analyzers. The parent ion of interest is selected and transmitted into the collision cell, where collisions between the gas molecules and the parent ions will occur. By this energy transfer, fragmentations of the parent ions occur, leading to the generation of charged and neutral fragments that may help structural elucidation.

Further details on fragmentation processes are available in the excellent book by Hillenkamp and Peter-Katalinic.\(^{(35)}\)

### 1.2 Coupling Matrix-assisted Laser Desorption/Ionization with Other Mass Analyzers

As already mentioned above, MALDI is characterized by a pulsed, but not a continuous generation of ions. Therefore, historically MALDI has always been coupled to TOF analyzers, since these analyzers are most suitable for monitoring the pulsed events taking place in the ion source. However, at least for more sophisticated analytical problems, there has been a strong need to combine the unique properties of the MALDI-ionization technique to other mass analyzers. Some of these reasons are as follows:

- to obtain more accurate mass determinations than achievable by simple TOF analysis;
- to improve the isolation selectivity of parent ions in MS/MS;
- to have access to multistage fragmentation (MS\(^n\)).

There were two important problems that had to be solved. The first problem was the pulsed ion generation of the MALDI source, but this problem could be overcome with the invention of more rapid pulsing lasers. Lasers pulsing in the range of kilohertz (thousand times per second) provide nearly a continuous ion stream. The second problem was to avoid the decay of the generated ions prior to their analysis. This problem was solved...
by “cooling” the ions of interest by collisional damping before their extraction by increasing the gas pressure in the ion source. These attempts are known as intermediate pressure or atmospheric pressure MALDI.\(^{36}\)

The comparison between vacuum and (in particular) atmospheric pressure MALDI extends further the knowledge of fragment ion generation and may help identify the structure of unknown compounds. However, peak intensities are generally higher in the vacuum MALDI spectra. A comprehensive comparison of vacuum MALDI and “atmospheric pressure” MALDI regarding “proteomics” was recently provided.\(^{36}\)

Although a comprehensive discussion of the different mass analyzers used in modern MS is clearly outside the scope of this article, a short summary is provided in Table 2. A more comprehensive treatment of this important topic is available in the recent book by Hillenkamp and Peter-Katalinić.\(^{35}\) Different ionization methods as well as vacuum and atmospheric pressure detection were recently compared.\(^{37}\)

### 1.3 Biological Molecules and Related Chemistry

In this article, the more general term “structural biology” is used to describe the molecules responsible for the highly ordered structures of living beings, e.g. the membranes of cells and connective tissues.\(^{38}\) Interestingly, a relatively small number of similar, ubiquitous molecules achieve the structural integrity seen in living organisms. This article gives a short overview of such basic molecules, including lipids (particularly phospholipids (PLs)), proteins, and carbohydrates (especially polysaccharides).

#### 1.3.1 Lipids

All higher organisms comprise a large number of cells that are highly differentiated into specific cell

types to fulfill individual tasks. However, all cells have certain common structures: cells are separated from the extracellular space by a membrane consisting of a highly ordered lipid bilayer. This cell membrane is essential for the transport of molecules in and out of the cell. The membrane is composed of a small number of different lipid classes (1–3), mainly phosphatidylcholine (2; PC), phosphatidylserine (1; PS), and phosphatidylethanolamine (3; PE). All these lipids possess, besides their relatively hydrophilic polar headgroup, two lipophilic fatty acyl residues. It is very common that saturated and unsaturated acyl residues are located in \( sn-1 \) and in \( sn-2 \) positions, respectively (stereospecific numbering). (25)

This marked amphiphilicity enables such lipids to form the characteristic bilayer in an aqueous environment. The formation of this bilayer is a unique feature of PLs.

One main problem in the analysis of lipids of natural origin is that they consist of a variety of different fatty acyl residues, derived from the saturated palmitic acid (16:0) up to the highly unsaturated docosahexaenoic acid (22:6). (38) The acronym \((x:y)\) is the usual nomenclature for fatty acids and lipids. Here, “\(x\)” represents the number of carbon atoms and “\(y\)” the number of double bonds in the fatty acyl residues of the lipid. Sometimes, if no further distinction is required, both residues of a given lipid are combined in this nomenclature. For instance, “36:2” may indicate the presence of two oleoyl (18:1) residues or one stearoyl (18:0) and one linoleoyl (18:2) acyl residue. (39)

Although investigations of lipids have been neglected over a long period of time, there is growing evidence that lipids like phosphatidylinositol phosphates or phosphatidic acid (PA) and diacylglycerols (DAGs) (4–6, respectively) play an important role in signal transduction processes, where they serve as messenger molecules. (40) The increasing interest in lipids and their physiological relevance is also reflected by the introduction of the term “lipidomics.” (41,42)

1.3.2 Proteins

Proteins play an important functional role in all living organisms, especially as biocatalysts and receptors. Additionally, proteins are the macromolecules that allowed the evolution of higher animals, since without the introduction of an active transport mechanism for oxygen (hemoglobin and myoglobin), the size of an organism would be strictly limited by diffusion processes. (38) Finally, proteins form the largest part of the dry weight of the human body, since proteins are also important components of muscles and of connective tissues. In tissues such as skin, cartilage, bones, and tendons, collagen comprises a larger moiety, providing the mechanical stability of such tissues. (43,44) The analysis of proteins and peptides is one of the main applications of MALDI/TOF MS and there are some excellent reviews on this topic. (16,17,45,46) Consequently, protein analysis will be treated relatively lightly here and only some important examples will be given. The interested reader is also referred to some recent reviews dealing with mass spectrometric investigations of the structural biology of proteins. (35,47)
1.3.3 Carbohydrates

Simple carbohydrates like glucose, fructose, or saccharose are important “fuels” for living organisms. The polysaccharides mainly fill important structural roles. For example, they constitute the largest part of the exoskeleton of insects and marine organisms in the form of chitin and its deacetylated form, chitosan (7), a positively charged polysaccharide. It is thought that chitosan is the most abundant polysaccharide on earth. A similar, but negatively charged, polysaccharide in the flora is alginate (8), which is a widespread component of plants, e.g. brown algae. Polysaccharides like dextran (9) or starch are the storage form of carbohydrates in many living organisms; in addition, naturally occurring carbohydrates can be therapeutically, for example, heparin (10) as an anticoagulant. Although the contribution of polysaccharides such as chondroitin sulfate (CS) and hyaluronic acid (HA) ((11) and (12), respectively) in the connective tissues is relatively low, many diseases are thought to be linked with damage to carbohydrates in the connective tissue, e.g. rheumatic diseases with cartilage degradation. Since the number of patients suffering from rheumatic diseases is constantly growing, such processes are of great socioeconomic significance, and the analysis of relevant polysaccharides by MALDI/TOF will also be discussed.

2 ADVANTAGES OF THE ANALYSIS OF BIOMOLECULES

MALDI/TOF MS offers a nearly unique possibility to analyze very small quantities of biological (detection limits down to the zeptomole \((10^{-21}\) mole) range have already been reported), highly polar, and less-volatile macromolecules, such as proteins and carbohydrates. In comparison with other MS techniques, the extent of fragmentation reactions is extremely low and the molecular ions (i.e. “quasimolecular” ions) are detectable in most cases. This is an advantage in the analysis of crude mixtures such as extracts of biological tissues or body fluids. However, one should always be aware that individual molecules in mixtures may be detected with different sensitivities. A further advantage of MALDI/TOF MS is that mainly singly charged molecular ions are formed. This leads to mass spectra that are easy to interpret, since each individual molecule results in a single peak. It makes MALDI/TOF a suitable tool for the analysis of mixtures without previous separation of the individual components, although the suppression of less sensitively detectable compounds by more sensitively detectable compounds should be always considered. This will be outlined below in more detail.

Finally, MALDI/TOF mass spectra can be easily and quickly recorded and no extensive sample clean-up is needed. The commonly used buffers for sample preparation do not markedly influence the quality of the mass spectra. In this sense, MALDI is obviously superior to similar MS methods such as ESI, which is strongly affected by such impurities. Nevertheless, one should always bear in mind that all salts (in particular, polyvalent ions as \(\text{SO}_4^{2-}\), \(\text{Ca}^{2+}\), \(\text{PO}_4^{3-}\), etc.), buffers, and detergents deteriorate the achievable signal intensities and line widths. The solvent of choice is, therefore, distilled water.
3 INTERPRETATION OF A GIVEN MASS SPECTRUM

Although MALDI/TOF mass spectra are generally easy to interpret, a few remarks on the characteristic features of MALDI/TOF spectra are useful. All modern MALDI/TOF mass spectrometers directly calculate the mass-to-charge ratio of the unknown compound from the TOF, which is the actually measured quantity. The number of counts (i.e. the number of ions reaching the detector) is normally plotted against the mass-to-charge ratio. In most standard measurements, the number of counts must not be overestimated since this value is influenced by many parameters, in particular, the applied laser strength.\(^{(53)}\) The number of counts is also difficult to reproduce because of the inhomogeneity of the analyte–matrix mixture\(^{(54)}\) and, therefore, the inhomogeneity of crystal formation.

The accessible mass resolution of MALDI/TOF spectra depends strongly on the individual compounds: high-molecular-weight compounds do not yield isotopically resolved peaks, but these can be obtained if substances with a lower molecular weight (up to about 4 kDa) are investigated. As a typical example of a compound yielding isotopically resolved peaks, the expanded region of a spectrum of an aqueous solution of adenosine triphosphate (ATP) recorded with 2,5-dihydroxybenzoic acid (DHB) as matrix is shown (Figure 5).

Since ATP possesses negatively charged phosphate groups, positive (Figure 5a) as well as negative ions (Figure 5b) are produced upon laser irradiation. MALDI/TOF spectra often represent the content of ions within the sample, leading to characteristic adduct ion signals. As one can clearly see from the mass difference of 22 Da, both spectra in Figure 5 were recorded in the presence of large quantities of Na\(^+\), which compete with protons for the binding site at the phosphate group (M – H\(^+\) + Na\(^+\)). The fact that ATP gives more than a single (isotopically resolved) peak is very typical for a biological environment. According to its monoisotopic mass of 551 Da for the disodium salt, the corresponding protonated ion (M + H\(^+\); \(m/z = 552\)) is easily found in the positive ion spectrum. However, this peak is accompanied by four additional peaks arising from an exchange of the protons with Na\(^+\) (\(m/z = 574\) and 596) or the two Na\(^+\) with protons (\(m/z = 508\) and 530). The presence of five peaks is, therefore, typical for compounds with four negative charges. The negative ion mode provides a simpler spectrum, yielding only three intense peaks that are shifted compared with that seen in the positive ion mode to lower masses (less than 2 Da) as a consequence of the loss of two protons (e.g. \(m/z = 528\) instead of 530).

Of course, the sample may be purified prior to MALDI/TOF mass spectrometric characterization and the Na\(^+\) concentration may be decreased. However, according to our experience, it is nearly impossible to remove Na\(^+\) ions completely from biological samples. In cases of mixtures, where, for instance, H\(^+\) and Na\(^+\) adducts overlap and obscure an important mass region of the spectrum, the addition of an excess of CsCl is a convenient method of shifting masses of interest.\(^{(55)}\)

![Figure 5](https://via.placeholder.com/150)

**Figure 5** Positive (a) and negative (b) ion spectra of a 0.1 mg mL\(^{-1}\) sample of ATP in pure water. Spectra were recorded with a 10 mg mL\(^{-1}\) aqueous DHB matrix in the reflector mode of the mass spectrometer.
4 PREPARING SAMPLE–MATRIX MIXTURES

In most instrumental analytical procedures, the quality of the resulting spectra is influenced by a variety of different parameters, which have to be set appropriately; however, in MALDI/TOF methodology there are only two parameters that have a major impact on the quality of the mass spectra. These are the homogeneity of the sample–matrix cocrystals and the applied laser intensity; these determine the extent of fragmentation and, therefore, the quality of the spectra.(56)

Consequently, it is wise not to underestimate the preparation of the analyte–matrix layer because this is the most important step in MALDI/TOF analysis, although this procedure sounds simple.

4.1 How to Choose an Appropriate Matrix

The first MALDI/TOF mass spectra of proteins were successfully recorded by Karas and Hillenkamp(15) using nicotinic acid as a matrix. However, this substance is no longer considered to possess ideal properties for MALDI/TOF analysis since it exhibits a strong tendency to fragment. A large number of useful matrices are now available for different applications(11,27,57) and the MALDI user must carefully choose the matrix that is appropriately adapted for his requirements. Lists of suitable matrix compounds are, for instance, available in the MALDI book by Hillenkamp and Peter-Katalinic.(35)

Since all the compounds suitable as matrices have both advantages and disadvantages, in this article only a small number of common matrix compounds that are currently used in our laboratory and their most important analytical applications are discussed (Table 3).

Since we use a pulsed nitrogen laser emitting at 337 nm, all matrix compounds must show strong absorptions at this wavelength; however, there are also a number of matrix compounds that are suitable for IR lasers (e.g. glycerol or the widely used tris(hydroxymethyl)aminomethane (TRIS) buffer).(27)

Finding the best matrix is a rather empiric process and only a few guidelines can be given. No single matrix compound is suitable for all analytes. (27) Generally, DHB ((13), gentisic acid) is useful for small, particularly highly polar, molecules (e.g. for carbohydrates), since it has only a low tendency to fragmentation and represents a very “fast” matrix, i.e. the arising ions possess high initial velocity. (11) DHB dissolved in a solvent such as methanol is also suitable for the quantitative analysis of lipids. (58) Although different isomers of dihydroxybenzoic acid are known, only the 2,5-isomer is suitable as MALDI matrix. (58)

An additional advantage of DHB is that it can be used in the positive as well as the negative ion mode. In the field of protein and peptide research, however, DHB is used less often. In these cases, sinapinic acid ((14): 3,5-dimethoxy-4-hydroxycinnamic acid)(59) or α-cyanohydroxycinnamic acid (15) for smaller proteins(60) should be used in the positive ion mode and 2,4,6-trihydroxyacetophenone (16) when the negative ion mode is of special interest. (61) Mixtures of different matrices are also sometimes recommended. (62)

One should note that nowadays there are also “matrix-free” approaches that enable the evaluation of even small masses without interfering matrix signals. This topic has been very recently reviewed. (63) A quite similar approach is the use of graphite or even pencil lead as “matrix”. (64)

4.2 Finding the Appropriate Solvent–Analyte Mixture

The importance of the homogeneity of the analyte–matrix crystals in determining the quality of the MALDI spectra is a fact that is often neglected. Since the analyte–matrix cocrystallization from a solution containing both compounds depends on the solvent used, the choice of the solvent is most important. A “good” solvent in the context of MALDI/TOF MS is a solvent in which both analyte and matrix are readily soluble. It is also advisable to use highly volatile solvents, whereas the application of solvents with a high boiling point (e.g. dimethyl sulfoxide, DMSO) is not recommended. Since the matrix must isolate the analyte molecules from each other (to prevent aggregation) in addition to allowing ion formation, the sample–matrix mixture should homogeneously crystallize when the solvent evaporates. (16) In a poor solvent, one component (the matrix or the analyte) would crystallize prior to the other one, resulting in separation of analyte-rich and matrix-rich compartments. In many cases, mixtures of different solvents (e.g. trifluoroacetic acid (TFA), acetonitrile (ACN), and water) (53) have to be used, since the matrix is more readily soluble in less-polar
Table 3: Guidelines for the preparation of suitable analyte-sample mixtures for the most important classes of biological molecules

<table>

<td>Peptides + proteins</td>
<td>Sinapinic acid (10 mg mL(^{-1})) in a mixture of TFA, water, and ACN (1:4:5, v:v:v, or similar volume ratios). Sample preferably in pure water. α-Cyano-hydroxy-cinnamic acid can also be used.</td>
<td>Cover 1-µL sample solution with about 1.5-µL matrix solution. No phosphate should be used for the sample. Preferably use buffers like HEPES or TMEDA. Allow the sample–analyte mixture to crystallize slowly at ambient temperature (the application of a slight vacuum may help improve the homogeneity of crystallization).</td>
<td></td>
</tr>
<tr>
<td>Carbohydrates</td>
<td>Use a saturated DHB solution in water (about 10 mg mL(^{-1})) for high-molecular-weight carbohydrates or water–methanol (ethanol) mixtures for low-molecular-weight compounds. The use of arabinose osazone is also convenient in a number of cases.</td>
<td>Highly dependent upon the chemical structure of the carbohydrate under investigation (the analysis of neutral carbohydrates is much more easier than that of strongly acidic ones): Since carbohydrates and matrix differ considerably in their solubilities, the mixture tends to separate. Crystallization is normally very poor. The recrystallization of the mixture from a small quantity of ethanol may help improve the homogeneity of crystallization (difficult to perform!)</td>
<td></td>
</tr>
<tr>
<td>Lipids</td>
<td>DHB (0.5 M; 77.1 mg mL(^{-1})) in methanol (ethyl acetate may also be used, if less-polar lipids have to be analyzed). Sample should be dissolved in chloroform or in CHCl(_3)–CH(_3)OH mixtures.</td>
<td>Place ca. 1 µL of lipid sample on the sample plate, followed by an addition of 1 µL of matrix solution (caution: organic solvents will readily “spride” over the metal surface). Under an air stream, very homogeneous analyte–matrix crystals are formed.</td>
<td>Lipid and matrix compounds are readily soluble in the same (organic) solvent. This enhances the homogeneity of crystallization considerably. This makes lipids one of the most easy to analyze substance classes.</td>
</tr>
</tbody>
</table>

ACN, acetonitrile; HEPES, N-(2-hydroxyethyl)piperazine-N’-ethanesulfonic acid; TFA, trifluoroacetic acid; TMEDA, N\(_{3}\),N\(_{3}\),N\(_{3}\),N\(_{3}\)-tetramethylethylenediamine; DHB, 2,5-dihydroxybenzoic acid.

Solvents such as ethanol or ACN, whereas the analyte often requires highly polar solvents such as water (often also in the presence of a certain amount of acid). The higher the difference between the polarity of the analyte and that of the matrix, the more difficult it is to obtain a homogeneous sample–matrix mixture. Table 3 lists some appropriate solvents or solvent mixtures for different substance classes.

Since spectra are mainly recorded in the positive ion mode, a cationizing species is often added along with the matrix to increase the concentration of ionized species.\(^{(16)}\) Although biological samples nearly always contain cations such as alkali metals (Na\(^{+}\) and K\(^{+}\)), the addition (of low amounts) of TFA has been found to be useful for biological samples. Finally, mass spectra of biological samples always reflect the natural ratio between Na\(^{+}\) and K\(^{+}\) (e.g. in the used buffer). That means that H\(^{+}\), Na\(^{+}\), and K\(^{+}\) adducts are often simultaneously detectable in biological samples. However, an equilibrium exists between these different forms and that can be strongly
influenced by the addition of ions that occur naturally only at negligible levels (e.g. Cs$^+$).

### 4.3 Mixing the Matrix with the Analyte

There are two different methods for preparing a sample spot for MALDI. The first method is to mix sample with matrix and to transfer this mixture subsequently to the sample plate. Although frequently recommended, this method should only be used if pure solvents, not solvent mixtures, are used. With mixtures of solvents, one less-soluble component (usually the analyte) precipitates and is not easily detected. Consequently, direct mixing of analyte and matrix on the sample plate is often advisable. About 1 μL of analyte is transferred to the MALDI target, followed by 1 μL of matrix solution, which should be prepared shortly before use. Matrix solutions should never be stored over several hours since they change with time.

It is strongly recommended to add analyte before matrix; if the matrix is added before the analyte it may start drying before it mixes with the analyte, and this may result in uneven sample–matrix crystals. Touching the sample plate with the fingers or with the pipette tip must also be avoided since this may cause uneven crystallization. Finally, the surface of the sample plate is rather sensitive to mechanical or chemical treatments. During cleaning of the sample plate, actions such as brushing that could damage the surface of the plate should be avoided, as damage can also lead to uneven crystallization. The sample plate should not be put in solutions containing high concentrations of detergents or strongly alkaline or acidic conditions for more than a few minutes.

Recently, the so-called add-on technique has been introduced, which confers enhanced sensitivity. Here, only the matrix is primarily transferred to the sample plate. After crystallization of the matrix, the sample is added on top of the matrix crystal and gives a large signal when such a “hot spot” is directly hit by the laser and no signal when the laser does not. This technique has been successfully used in the field of lipid analysis. Unfortunately, the fluctuations from shot to shot are high.

As mentioned above, MALDI tolerates considerable amounts of buffer compounds, detergents, and salts. However, some common anions like sulfate or phosphate as well as high amounts of Na$^+$ strongly decrease molecular ion formation, whereas the influence of organic, nonionic buffers such as N-(2-hydroxyethyl)piperazine-N'-ethane sulfonic acid (HEPES) is only weak. The influence of different commonly used buffers and salts has recently been thoroughly investigated.

If the sample cannot be desalted prior to the measurement (e.g. by ion-exchange chromatography), the analyte–matrix mixture can be directly “washed” on the sample plate. This requires that the impurities are more readily soluble than the analyte itself. In this case, a small amount of water is added to the dried analyte–matrix mixture and is removed after about 10 s by sucking it off with a pipette. This process can be repeated several times. Another important method for the purification of contaminated samples prior to MALDI analysis is drop dialysis. Here, a few microliters of a protein sample are deposited on a membrane floating on top of pure water. This drop is retrieved after about 30 min with a micropipette. However, desalting the sample prior to its application to the sample plate is preferred. Very recently, specially designed pipette tips containing a layer of an ion-exchange resin, which allows the direct desalting of the sample, became commercially available (ZipTip™, Millipore). The protein solution of interest is prepared in diluted TFA. Under these conditions, proteins are positively charged and bind to the negatively charged resin, whereas all further neutral molecules and strong electrolytes as salts are not bound. After one or two washing steps of the resin, an alkaline solution is used for elution of the protein from the resin. Using this method, proteins can be easily purified and concentrated.

Highly diluted samples cannot be concentrated easily by evaporating the solvent, as potential impurities would be concentrated too. For that purpose, special “anchor” sample plates were developed and are commercially available now. These special targets have small hydrophilic islands, typically of 100–500-μm diameter, placed on a hydrophobic surface. The purpose of the hydrophobic surface is the prevention of the spreading of the sample solution over a large area: during crystallization, the applied solution contracts onto the hydrophilic islands, thereby concentrating the matrix and the analyte into a defined volume. If impurities are significantly less polar than the analyte of interest, a separation between both may be also achieved by this simple procedure.

### 5 RECORDING MASS SPECTRA

On a modern MALDI/TOF mass spectrometer, the acquisition of mass spectra is very simple because only a few parameters have a major impact on the quality of the spectra. As a guideline for recording the very first MALDI/TOF spectra, it is strongly recommended to use the acquisition files provided by the manufacturer and a sample of known composition. The first aim should be to obtain a spectrum with a sufficient signal-to-noise ratio (S/N) and an adequate mass resolution as a starting point for further optimization of the parameter set.
5.1 Important Instrumental Parameters

All adjustable parameters are highly dependent upon the type of spectrometer used; therefore only some general guidelines can be given. Since modern mass spectrometers often provide the possibility of working in a number of different acquisition modes (positive/negative ion detection mode, continuous or DE and, finally, reflector or linear mode), the chemical composition and the molecular weight of the analyte are of special interest.

For molecules exceeding a molecular weight of about 4000 Da, the easiest way to implement the linear mode with continuous extraction should be used. This method provides the highest sensitivity and only a low amount of fragmentation because the path of flight is short. However, the peaks are broader than in the DE mode because of the significant velocity distribution of ions that is least partially compensated using the DE mode. Since high-mass molecules yield broad peaks through strong adduct formation, mass resolution is not so important. For such analytes, the accelerating voltage should also be set to its maximum value (often 25 kV), providing the highest sensitivity. The so-called “low mass gate” is used to avoid the saturation of the detector with low-molecular-weight ions derived from matrix degradation. This gate prevents the activation of the detector until ions greater in mass than the selected value pass the detector. Setting the low mass gate too close to the peaks of interest should be avoided because under these circumstances peak shapes as well as the achievable mass accuracy may be negatively affected. If an expected peak at lower mass is missing or is poorly resolved, the same spectrum should be recorded without the low mass gate and the individual spectra compared. All other parameters that have to be set for the use of DE and the reflectron (both recommended for smaller molecules) are given in the manual of the spectrometer. It is outside the scope of this review to give a comprehensive overview on this topic.

5.2 Laser Power

Besides homogeneous analyte–matrix crystallization, the applied laser power is the second parameter that has a major impact on the quality of the mass spectra. It is strongly recommended to set this parameter as low as possible within the power levels required. Whereas higher laser power often confers an enhanced signal-to-noise (S/N) ratio, it also causes more fragmentation and a decreased mass resolution; using a lower laser power (only a small amount over the threshold level) improves the mass resolution, especially the quality of the baseline. Furthermore, increased laser power leads to enhanced intensities of metal and matrix adducts, confers enhanced formation of doubly and triply charged ions (at one half and one-third of the expected molecular mass) and, finally, leads to the formation of dimers (at the double molecular mass). The required laser power strongly depends on the substance class that is under investigation. For example, it has been shown that the minimum, or threshold, laser irradiance necessary to produce protein ions from a sample is about 10 mJ cm$^{-2}$ for a 10-ns laser pulse width. Near the threshold, ion production falls off with the fifth power of laser irradiance. Generally, a laser intensity of about 10% over threshold is a suitable setting for most measurements.

Whereas oligopeptides give a strong signal even at relatively low laser intensity, acidic carbohydrates require maximum laser intensity. Increased laser strength is also required when a large amount of ionic impurities are present. The applied laser intensity is the main reason why spectra obtained at different MALDI spectrometers are difficult to compare: most suppliers provide only a relative scale of the used laser intensity and, therefore, these settings are difficult to compare with those on another mass spectrometer.

5.3 Standards of Mass Calibration

In MALDI/TOF MS, calibration adjusts the mass assignment for the acquired data. The software of most mass spectrometers includes a default calibration routine (only the matrix has to be specified) that provides an adequate mass accuracy (deviation approximately 0.1%) for many applications. However, if optimum mass accuracy is required, a calibration based on the observed TOF of a known mass of a special calibration standard should be performed. This standard must have a similar mass and should be of similar structure to the analyte. For example, a lipid should serve as calibration standard when lipids are investigated. The calibration standard may be measured individually (external calibration) or be included in the analyte (internal calibration). The basic equations used in the calibration process were described in more detail by Juhasz et al. These authors determined the initial velocity of ions in specific matrices and introduced corresponding correction terms. This correction is particularly necessary if different delay times are used in the DE mode.

For the first experiments to calibrate the mass spectrometer, the use of a known low-molecular-weight substance (e.g. an oligopeptide that gives highly resolved peaks) is strongly recommended. Using this substance, the effects of different settings on the quality of the calibration file should be tested. The use of the linear mode and the reflectron mode requires different calibration files and sometimes (particularly if larger targets are used) differences are also found depending on the sample position on the sample plate.
Mass accuracy is typically given in parts per million (ppm). For example, 50 ppm means that the real mass of an ion measured to 1000 Da has a predicted error margin of ±50 mDa. One should note that the mass accuracy is also determined by the number of data points that are sampled for each mass spectrum as the number of points determines the center of a peak as accurately as it can be determined.\(^{(73)}\)

### 6 APPLICATION OF MASS SPECTROMETRY TO THE ANALYSIS OF BIOMOLECULES

The following short overview of the most important, biologically relevant substance classes describes experiments with isolated components, where possible spectra of biological samples, such as body fluids or cell suspensions, are described as examples of the applications as well as the limitations of MALDI/TOF analysis.

#### 6.1 Small Molecules and Common Impurities of Biological Samples

Although not originally developed for such purposes, MALDI/TOF MS is also suitable for the detection of low-molecular-weight compounds with masses of a few kDa occurring typically in biological samples (e.g., carbohydrates). Such low-molecular-weight compounds (e.g., oligopeptides) were the first compounds where the possibilities of quantifying MALDI/TOF mass spectra were demonstrated.\(^{(74)}\) Although low-molecular-weight compounds often interfere with the matrix, such compounds are usually easily detected because their molecular weight is known. Typical examples of such molecules are reduced nicotinamide adenine dinucleotide (NADH), ATP (Figure 5), different kinds of lipids and PLs, and carbohydrates like saccharose or glucose, all of which can be found in most cell and tissue extracts.

Because of its high sensitivity, MALDI also detects a number of impurities in biological samples.\(^{(75)}\) A very common impurity, especially in commercially available biochemicals, is poly(ethylene glycol) (PEG). This polymer plays a major role as an additive in a number of biological processes,\(^{(76)}\) such as the precipitation of proteins from solutions. Fortunately, PEG can be easily distinguished as it has a typical peak pattern, reflecting the molecular weight of the repeating unit and the distribution of the molecular weight.\(^{(34)}\) PEG is mainly synthesized from ethylene glycol by polycondensation or from ethylene oxide by anionic “living” polymerization. The molecular weight of its repeating unit \(\text{−CH}_2\text{−CH}_2\text{−O−} = 44 \text{Da} \) and this can be identified among the peaks of the spectrum.

In Figure 6, the influence of the acquisition parameters and the molecular mass of PEG is shown. The spectra in (a) and (b) were obtained with a PEG 1500 sample, whereas (c) used a PEG 6000 sample.

Spectra (b) and (c) were recorded in the linear mode, and (a) was recorded using a reflectron. It is evident that (a) exhibits improved mass resolution since the reflectron enhances the flight path and compensates for the differences in flight time of ions with equal mass-to-charge ratios but different initial velocity.

The linear mode spectrum is characterized by decreased mass resolution but higher sensitivity. There may be slight differences between the determined mass-to-charge ratios in the linear and the reflectron mode (cf. Figure 6a and b); consequently, different calibration files have to be used for the two modes.\(^{(16)}\) Although the use of the reflector mode would be valuable for the analysis of synthetic polymers and, therefore, for industrial research, polymers with a higher degree of polymerization cannot be measured in this way. As shown in Figure 6 for spectra obtained in the same manner but with differing degrees of polymerization of PEG (b and c), the larger polymer (average 6 kDa) has a broad mass distribution that prevents identification of other individual molecular species. However, it has been shown that the application of more sophisticated techniques (such as DE conditions) still allows the acquisition of highly resolved mass spectra of polymers (e.g., PEG 20 000).\(^{(34)}\) Again, the matrix used plays the most important role and great care is needed to select a suitable compound (DHB is good for many synthetic polymers).\(^{(57)}\) Detergents based on ethylene glycol such as triton, Brij, Myrj, Tween, and Tagat are often used to solubilize membrane proteins. Their mass spectrometric characteristics were investigated very recently, and it could be clearly shown that all these detergents give very typical mass spectra, allowing the differentiation of the individual compounds.\(^{(77)}\)

In addition to such high-molecular-weight impurities, most biological samples contain a large number of compounds (buffer salts, detergents, small carbohydrates like glucose, amino acids, etc.) that possess a molecular weight similar to the matrix. Although these compounds can be eliminated to some extent by the low mass gate, a large amount of such molecules may affect the quality of mass spectra by adduct formation and may considerably reduce ion formation.\(^{(16)}\)

Finally, it must be kept in mind that most matrix compounds undergo a slow polymerization process, even in the solid state and especially in aqueous solution. For example, cinnamic acid derivatives yield upon aging (owing to the presence of the alkenic residue) intense peaks of polymeric products (between about 11 and 18 kDa). Therefore, it is advisable that all matrix solutions are always freshly prepared. Additionally, the starting
material should be replaced after a fixed time by a new charge.

It should also be realized that UV-absorbing compounds can be characterized by MALDI/TOF even in the absence of an additional matrix. Under these conditions, the compound under investigation serves simultaneously as matrix and as analyte. Here, the term LD spectrum instead of MALDI should be used. Unfortunately, this is only possible for compounds of molecular weights up to about 3 kDa. Beyond this size, the energy needed for resonant absorption is greater than the energy required for dissociation of the molecule.

6.2 Proteins

One of the main applications of MALDI/TOF MS is the investigation of proteins, especially oligopeptides. The main advantages of MALDI/TOF in this context are the simple experimental setup, a rapid procedure, and, finally, the high mass resolution (e.g. in comparison with electrophoresis). These advantages of MALDI/TOF have already led to the introduction of highly automated mass spectrometers for the analysis of unknown proteins. Here, the protein of interest is subjected to different enzymatic digestions, and the digests (usually obtained by treatment with trypsin) are subsequently analyzed by MALDI/TOF (“peptide mapping”). The concept of peptide mass mapping for protein identification by combination of MS and protein sequence database searching was already proposed in 1993 by different research groups. This peptide mass fingerprinting (PMF) approach of protein analysis is also referred to as the “bottom-up” approach. Since there are many papers available on this subject, this is not outlined here in more detail. Detailed descriptions of

Figure 6  Comparison of the MALDI/TOF mass spectra of commercially available PEG 1500 (a,b) and PEG 6000 (c). Spectrum (a) was recorded with a reflectron and in the DE mode, whereas (b) and (c) were recorded in the linear mode. A 0.1 mg mL\(^{-1}\) PEG sample and a 10 mg mL\(^{-1}\) DHB solution in H\(_2\)O were used. Note the higher intensities but significantly enhanced line widths if the spectra are recorded under “linear” conditions.
methodological approaches\(^{(81)}\) as well as excellent reviews are also available.\(^{(82)}\) Suppliers of mass spectrometers have also significantly contributed to the progress in this field, and nowadays, highly automated devices equipped with nano-LC systems coupled to Robot MALDI-spotters are commercially available.

The reader should note that the reliable analysis of peptide mixtures obtained by enzymatic digestion of a certain protein requires very high mass accuracy as inaccuracy increases the number of hits upon database searching significantly. Although very large databases are nowadays available, not all obtained peptides will be actually available. Therefore, “de novo sequencing” of such an unknown peptide by using the interpretation of peptide fragment patterns is often necessary. Finally, isobaric amino acids such as leucine or isoleucine are still difficult to differentiate by MS methods.

As one representative example of a MALDI/TOF mass spectrum of an intact protein, Figure 7 shows the positive ion mass spectrum of a commercially available serum albumin (molecular weight approximately 67 kDa).

This spectrum is relatively simple to interpret and consists only of three different peaks. Whereas the most intense peak at the highest mass-to-charge ratio represents the singly charged molecular ion, the remaining two peaks at about 33 and 22 kDa correspond to the doubly and triply charged molecular ions, which appear with decreasing intensity compared with the singly charged molecular ion. Such multiple-charged ions are found in most cases when proteins are investigated and are affected by the applied laser intensity only to a small extent. By comparison, the formation of protein dimers, which is clearly reflected by the formation of peaks at the double mass-to-charge ratio (for albumin at approximately 134 kDa, data not shown), is highly influenced by the applied laser intensity and can be minimized by using a lower intensity.\(^{(17)}\) A high extent of dimer formation even at moderate laser intensity may also indicate that the protein concentration within the sample is too high and that the sample should be further diluted with the solvent or the matrix.

One further recent application of MALDI/TOF MS is the detection of covalently modified amino acids in larger proteins (“posttranslational modification”). More than 200 different posttranslational modifications are currently known, and they give rise to a characteristic mass increase of certain amino acid residues, and thereby, the peptides obtained after an enzymatic digestion of the protein.\(^{(83)}\) For instance, the detection of lysine methylation,\(^{(84)}\) tyrosine sulfation,\(^{(85)}\) and tyrosine phosphorylation\(^{(86,87)}\) has been reported. Since phosphorylation events in a biological environment correlate with protein kinase activity, this also allows enzyme activities to be determined by MS.\(^{(88)}\)

Unfortunately, proteins containing large proportions of carbohydrates (e.g. glycoproteins) are still rather refractory to MS analysis. The problem here is that the signals of glycosylated proteins are extremely broad and reflect the large amount of heterogeneity in the carbohydrate moiety.\(^{(16)}\) MALDI/TOF mass spectrometers are, however, generally able to resolve individual glycoforms only for small proteins containing a limited number of glycans, preferably attached only to one site. One example is ribonuclease B (15 kDa) with five mannose glycans at a single glycosylation site.

Treatment of such glycosylated proteins with specific glycosidases and the subsequent remeasurement of the mass spectra often provides useful information on the number and the chemical structure of the carbohydrates that are removed by the enzyme.\(^{(89)}\)

![Figure 7](image)

**Figure 7** MALDI/TOF mass spectrum of a 1 mg mL\(^{-1}\) solution of human serum albumin. For this spectrum 1 \(\mu\)L of protein solution (1 mg mL\(^{-1}\)) was transferred to the sample plate followed by 1 \(\mu\)L of matrix solution (10 mg mL\(^{-1}\) sinapinic acid in a water–ACN–TFA mixture).
A further important advantage of MALDI in the field of protein analysis is that the quaternary structure of a protein can be elucidated.\textsuperscript{(90,91)} For example, the tetrameric, noncovalently bound subunits of proteins like glucose isomerase and streptavidin could be clearly detected by MALDI/TOF.\textsuperscript{(90)} Dissociation and association of such complexes can easily be followed when different solvents are used. Pure water favors the association of the complexes, whereas the addition of organic (less polar) solvents such as ethanol leads to dissociation of the protein complexes.\textsuperscript{(91)} This exciting application of MS is still in its infancy, but currently, the number of papers dealing with the detection of noncovalent complexes is increasing strongly.\textsuperscript{(92)} Very recently, it was shown that noncovalent protein–protein complexes can be easily analyzed if neutral matrix solutions (instead of commonly acidified solutions) are used.\textsuperscript{(92)} For a comprehensive review of this topic, see the excellent paper by Bolbach.\textsuperscript{(93)}

Traditionally, hydrogen exchange has been used in conjunction with nuclear magnetic resonance (NMR). However, it is now also possible to use MS to measure hydrogen exchange. The method is based on the fact that each protein contains acidic hydrogen atoms capable of exchanging with the solvent (−OH, −NH, −SH). If D\textsubscript{2}O is used as the solvent, the heavier mass of H\textsubscript{2}O leads to dissociation of the complexes, whereas the addition of organic (less polar) solvents such as ethanol leads to dissociation of the protein complexes.\textsuperscript{(91)} This exciting application of MS is still in its infancy, but currently, the number of papers dealing with the detection of noncovalent complexes is increasing strongly.\textsuperscript{(92)} Very recently, it was shown that noncovalent protein–protein complexes can be easily analyzed if neutral matrix solutions (instead of commonly acidified solutions) are used.\textsuperscript{(92)} For a comprehensive review of this topic, see the excellent paper by Bolbach.\textsuperscript{(93)}

Unfortunately, it must be noted that most biological samples are not sufficiently concentrated for a direct MALDI/TOF mass spectrometric analysis (e.g., the enzymes released by different cell types upon stimulation).\textsuperscript{(101)} Under these conditions, only highly abundant proteins like human serum albumin can be detected; the signals arising from proteins occurring in lower concentrations are suppressed by the highly abundant proteins. One of the major advantages of MALDI/TOF MS is, however, that proteins separated by classical electrophoresis can be subsequently used for MALDI/TOF analysis;\textsuperscript{(102)} in this way, the advantages of protein separation and MS methods can be combined. In recent years, special interest has been paid to such applications and a number of publications on this topic are now available. Nevertheless, the main problem in the field of protein analysis is still the rather low reproducibility of MALDI/TOF mass spectra. Different approaches have been tried to improve the homogeneity of the analyte–matrix crystals, for example by the application of nitrocellulose membranes\textsuperscript{(103)} and electrospray sample preparation.\textsuperscript{(104)}

### 6.3 Carbohydrates/Polysaccharides

Whereas MALDI/TOF MS has become an established tool in protein chemistry, there are not many reports on the feasibility of MALDI/TOF for the analysis of carbohydrates.\textsuperscript{(23)} This lack of experimental data is primarily because of two reasons. First, many proteins have a rather fixed molecular weight (if posttranslational modifications are neglected), whereas naturally occurring polysaccharides possess a considerable distribution of their molecular weights. This results in a decreased concentration of the individual species and, consequently,
sensitivity for carbohydrate detection is considerably diminished.\(^{(105,106)}\) Second, many physiologically relevant polysaccharides do not occur as such, but are mostly esterified with phosphorus or sulfuric acid.\(^{(107)}\) The resulting phosphates and sulfates possess a higher polarity than the uncharged polysaccharides, and desorption as well as ion formation is strongly decreased. Because this derivatization leads to serious problems, at least under standard experimental conditions, up to now, mainly low-molecular-weight oligosaccharides like dextran that carry no additional charges have been characterized.\(^{(106)}\) A typical spectrum of an aqueous solution of dextran (which is a homopolymer composed of glucose residues that are mainly \(1 \rightarrow 6\) glycosidically linked)\(^{(43)}\) recorded in an aqueous DHB matrix is shown in Figure 8.

Dextran shows a mass spectrum that resembles the PEG spectrum, with the mass difference of the two individual peaks at 162 Da.\(^{(106)}\) This value corresponds to the molecular weight of the glucose subunit (180 Da) minus one water molecule (18 Da), which is eliminated by the formation of the glycosidic linkage. Therefore, the mass spectrum can be directly used to estimate the number of repeating units of the polysaccharide although smaller molecules are more sensitively detected than larger ones. In Figure 8(b), the matrix as well as the dextran solution has been prepared in deuterated water (\(\text{D}_2\text{O}\)) to show the effects of isotope exchange. As clearly seen, the use of the deuterated solvent shifts all peaks to higher masses and multiplies the number of peaks (mass difference is 1 Da) through the competition of hydrogen and deuterium for the number of exchangeable protons within the dextran molecule. This behavior enables the operator to estimate the number of acidic residues within the polysaccharide. The theoretical basis and some applications of such exchange processes were recently discussed.\(^{(108)}\) At the same time, the deuterium/hydrogen exchange results in a poorer signal because of increased noise owing to the lower numbers of the individual species.

Although commonly used matrices like DHB can be used for the analysis of small carbohydrates, methods for the improvement of sensitivity and resolution of saccharides are still needed. However, very recently, it has been shown that high-molecular-weight carbohydrates (~70 kDa) can also be analyzed by MALDI/TOF if an extremely high matrix/analyte ratio is used (DHB in about \(10^5\)-fold molar excess over the analyte).\(^{(109)}\) Unfortunately, the resulting mass resolution is extremely poor and the only information obtainable is an approximate estimation of the molecular weight. Consequently, for carbohydrate analysis, new matrix compounds yielding higher mass resolution and an enhanced S/N are essential for future applications. One recent proposal for this problem has been the use of arabinose osazone as matrix.\(^{(110,111)}\) The idea behind this is that osazones (the reaction products between reducing carbohydrates and phenylhydrazine) are classical well-crystallizing compounds that are often used for the derivatization of carbohydrates. It is, therefore, assumed that osazones possess ideal crystallization properties in a mixture with different carbohydrates. The authors demonstrated that the use of arabinose osazone gave spectra with an improved S/N compared with spectra obtained with DHB.\(^{(110)}\) An additional advantage of this application is the very high tolerance of the osazone matrix toward salts and other contaminants.

A very intriguing example for the MALDI/TOF analysis of complex carbohydrates was an investigation of

---

**Figure 8** Comparison of the MALDI/TOF mass spectra of commercially available dextran (MW \(\approx 1500\)). Both spectra were recorded with a reflectron and in the DE mode. (a) Matrix and analyte dissolved in \(\text{H}_2\text{O}\). (b) Matrix and analyte dissolved in \(\text{D}_2\text{O}\).
milk.\textsuperscript{(112)} Although initial separation of the different carbohydrate classes was required, the authors succeeded in the identification of a large number of different, so far unknown, carbohydrates. It is especially interesting that, even under these nonoptimized conditions, polysaccharides up to a molecular weight of about 8 kDa could be detected and their structure elucidated.

It is even harder to analyze acidic polysaccharides. Although some attempts have been made to characterize strongly acidic carbohydrates such as heparin (10)\textsuperscript{(113,114)} or CS (11)\textsuperscript{(115)} by MS, all these studies used a previous derivatization of the carbohydrate sample to enhance desorption and volatility. For MALDI/TOF analysis of acidic carbohydrates, it is strongly recommended to add an artificial, positively charged (caused by e.g. a high arginine content) oligopeptide to the carbohydrate solution.\textsuperscript{(116)} This peptide binds noncovalently to the negatively charged groups of the polysaccharide, reducing the negative charge of the analyte. The resulting ionic complexes easily desorb and can be conventionally analyzed by MALDI/TOF. However, all molecular weights have to be corrected for the (known) mass of the peptide. Comparable spectra may also be obtained by the use of positively charged spermine.\textsuperscript{(117)}

Very recently, it was found that strongly acidic oligosaccharides (up to a molecular weight of about 2 kDa) can be directly characterized by MALDI/TOF. Such oligosaccharides are usually produced by the enzymatic treatment of the corresponding polysaccharide with specific or less-specific saccharidases, for example, hyaluronidase\textsuperscript{(118,119)} or chondroitinase.\textsuperscript{(119,120)} If this digestion is carefully performed, the reproducibility of mass spectra is high; it was shown, in the case of selected hyaluronan oligosaccharides, that quantitative evaluation of spectra is even possible.\textsuperscript{(121)} In Figure 9, some selected spectra of HA-6 recorded at different concentrations are shown.

The spectra (A) correspond to the positive ion spectra, whereas spectra (B) represent the negative ion spectra. It is obvious that the negative ion detection mode is more sensitive: considering the lowest concentration of HA-6 (traces, Figure 9c and f), the positive ion (Figure 9c) spectrum is characterized by a poor S/N ratio that is close to the detection limit. It is also to be noted that the peaks detectable in Figure 9(a) (marked with asterisks) at m/z = 1233 and 1245 are not caused by HA, but are stemming from the applied DHB matrix (7 DHB − 6 H\textsuperscript{+} + 7Na\textsuperscript{+}). It is well known that DHB, under conditions of laser irradiation, gives some charged oligomers.\textsuperscript{(112)} By defining any arbitrary S/N ratio as threshold, detection limits can be easily obtained. Selected data are shown in Figure 10:

It is evident that the detectability decreases when the mass of the HA of interest increases, indicating that larger amounts are required when HA oligosaccharides with higher masses are investigated. It is also clear that this effect is more pronounced if the positive ion spectra are analyzed: since each polymer repeat unit (composed of one glucuronic acid and one N-acetylglucosamine unit) adds one negative charge, the sensitivity difference between the positive and negative detection mode increases if the mass of the investigated HA increases.\textsuperscript{(121)}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure9.png}
\caption{Positive (A) and negative ion (B) MALDI/TOF mass spectra of aqueous solutions of HA-6 relative to the amount of HA on the MALDI target. Solutions of 3.13 ng (a,d), 0.41 ng (b,e), and 0.05 ng (c,f) were deposited onto the sample plate. All spectra were recorded in the linear detection mode for optimum sensitivity. All peaks are marked according to their individual m/z ratios. Peaks arising from the DHB matrix are marked with asterisks. (Figure was published in ref. 121, © Elsevier 2006.)}
\end{figure}
deviations were estimated to be of the order of units) of the individual investigated hyaluronan fragments. The sample plate relative to the size (number of monosaccharide preparations.

was also used to analyze the hyaluronan content in CS based on ESI MS and selective enzymatic digestion to obtain defined oligosaccharides. A similar approach weights higher than a few kilodaltons is impossible, and a direct analysis of acidic carbohydrates with molecular detection mode when HA fractions with a higher molecular weight were investigated. (Figure was published in ref. 121, © Elsevier 2006.)

Since our group is mainly interested in the investigation of degradation processes of the extracellular matrix of cartilage during rheumatic diseases, the analysis of negatively charged oligosaccharides would be of great significance for progress in this field. It is known that the strongly acidic polysaccharides of cartilage (HA, CS, and keratan sulfate) are depolymerized during inflammation, under the influence of reactive oxygen species (ROS) and different enzymes. Owing to the large variety of ROS and enzymes that both occur under in vivo conditions, however, the investigation of such processes is very difficult. Nevertheless, MS has proven usefulness for the investigation of degradation processes of polysaccharides of cartilage by ROS on a model level. However, one should always keep in mind that a direct analysis of acidic carbohydrates with molecular weights higher than a few kilodaltons is impossible, and details of previous enzymatic degradation are necessary to obtain defined oligosaccharides. A similar approach based on ESI MS and selective enzymatic digestion was also used to analyze the hyaluronan content in CS preparations.

One promising approach for the cure of degenerative joint diseases is the transplantation of stem cells or chondrocytes (the cartilage cells that synthesize the extracellular matrix) into the joint of the affected patient to replace the damaged cartilage. An alternative is the transplantation of bioengineered cartilage and this interesting topic has been recently reviewed. Unfortunately, it is very difficult to assess under which conditions chondrocytes generate a maximum of extracellular matrix, as the standard histological approaches provide only a semiquantitative information. It was shown recently that the de novo synthesis of CS may be easily determined by MALDI/TOF MS subsequent to cartilage degradation by chondroitinase ABC (an enzyme that cleaves CS A, B, and C) that produces a single unsaturated disaccharide from the CS of cartilage that can be very easily monitored by means of a positive and – more sensitive – negative ion MS. In these studies, it could be shown that not only the amount of CS can be easily determined but information on the ratio between the 4- and the 6-sulfate isomer (that occur both under in vivo conditions) can also be obtained, as the fragment ion spectra from the 4- and the 6-sulfate isomer differ significantly.

This is schematically shown in Figure 11. Chondroitin sulfate was completely digested with chondroitinase ABC and the negative ion spectra directly recorded from the digest. The protonated and the sodiated forms of the resulting unsaturated disaccharide are shown in Figure 11. Both ions were subjected to further PSD analysis: it is obvious that both spectra differ considerably, although the same molecule, but only different adducts are analyzed. In particular, the peaks at \( m/z = 282 \) and 300 that appear exclusively in the upper spectrum are of interest because they are derived exclusively from the 6-sulfate and the 4-sulfate, respectively. The reference data were obtained by using electrospray ionization/collision-induced dissociation (ESI/CID). However, such a sophisticated equipment is obviously not absolutely required, as the same information can be also obtained by using the simple PSD technique that is routinely available on all MALDI devices equipped with a reflectron.

However, this method has some disadvantages too: for instance, PSD suffers from relatively low sensitivity, and only moderate resolution can be obtained. Additionally, the need to stitch together spectra derived from several reflector voltages makes calibration rather difficult. It is also important to note that the extent of fragmentation depends significantly on the applied matrix. “Hot” matrices such as α-cyano-4-hydroxy cinnamic acid (4-HCCA) usually catalyze considerable fragmentation, whereas “cooler” matrices as DHB or Trihydroxyacetophenone (THAP) do not. A more comprehensive discussion of this aspect was provided by Pfenninger et al.

In summary, so far the main application of MALDI/TOF in the field of carbohydrate research is for the analysis of well-defined carbohydrates occurring in complex molecules such as glycolipids or glycoproteins. There are only few reports on the analysis of naturally occurring, acidic oligo or polysaccharides. The main problem, besides the distribution of molecular weights,
6.4 Lipids

Although the importance of lipids has tended to be overlooked, interest has recently increased with the realization that rarer lipids have important roles in biological modulation.\(^{(133)}\) While common PLs like PC (2), PS (1), and PE (3) are essential constituents of the cell membranes,\(^{(38)}\) rare lipids like phosphatidylinositol phosphates (4), DAGs (6), and PA (5) are assumed to play a very important role in signal transduction processes.\(^{(40)}\) Finally, highly unsaturated fatty acids, e.g. arachidonic acid, are important for the synthesis of essential molecules like prostaglandins or leukotrienes.\(^{(24)}\)

Whereas nearly all available ionization methods of MS have been already used in MS lipid analysis, nowadays, only two of them play a major role, namely, ESI\(^{(134)}\) and APCI\(^{(135)}\) (atmospheric pressure chemical ionization). Reviews on the advantages and drawbacks of the individual methods are also available.\(^{(1)}\) MALDI/TOF
MS is also increasingly used in the field of lipid analysis, although it took some time to explore the advantages and capabilities of this method after some pioneering studies in the middle of the 1990s. This is somewhat surprising, as the most important requirement of MALDI/TOF MS, an even crystallization of analyte and matrix, is fulfilled by lipids: these apolar molecules are insoluble in water and, therefore, all operations may be performed in organic solvents only, where a majority of common UV MALDI matrices are also easily soluble. This provides very homogeneous analyte–matrix crystals.

In Figure 12, two different wells on a MALDI sample plate containing crystals of an aqueous analyte–matrix mixture and an organic analyte–matrix mixture are shown.

Figure 12(a) shows a typical example of a carbohydrate–matrix (aqueous DHB) mixture with uneven crystallization; Figure 12(b) shows a lipid–matrix mixture for which a 1-µL sample of lipid in chloroform was transferred to the sample plate, and a 1-µL droplet of the matrix solution (DHB in methanol) was subsequently added. It is clear that the latter mixture provides by far more homogeneous crystallization accompanied by good shot-to-shot reproducibility.

To give the reader an idea about typical spectral patterns of lipids, some selected positive and negative ion (indicated by ‘’+’’ and ‘’−’’) MALDI-TOF mass spectra of three physiologically relevant PLs (PC 16:0/18:1, PE 16:0/18:1, and PS 16:0/18:1) as well as triolein are shown in Figure 13.

Considering first the positive ion spectra, significant differences are obvious: PC 16:0/18:1 provides two peaks

![Figure 12](a) Comparison of two different wells of the MALDI sample plate. (a) The crystallization pattern of a typical aqueous carbohydrate sample with DHB as matrix. (b) A typical dried mixture of DHB (0.5 M in methanol) and a lipid, crystallized from chloroform.

![Figure 13](a) Selected positive and negative ion (indicated by ‘’+’’ and ‘’−’’) MALDI-TOF mass spectra of three physiologically relevant phospholipids (PC 16:0/18:1, PE 16:0/18:1, and PS 16:0/18:1) as well as triolein. It is to be noted that all lipids are detectable as positive ions, whereas only acidic lipids provide significant yields of negative ions. The more marked contribution of matrix signals (marked with asterisks) to the negative ion spectra is obvious. In the inserts labeled “a” and “b”, the expanded regions of the peak at m/z = 551 and 784.6 are shown. It is obvious that the different chemical formula of the DHB matrix and the lipid are clearly reflected by the distribution of the isotopes.
at \( m/z = 760.6 \) and 782.6 according to the \( H^+ \) and the \( Na^+ \) adduct of the neutral PC molecule. There are no further signals that would point out fragmentation. This is in agreement with our previous work\(^{25}\) and the work from other groups.\(^{138}\) There are not even traces of lysophosphatidylcholine (LPC) that is generated from PC by the loss of an acyl residue. This makes MALDI a useful tool to determine LPC – an important lipid second messenger – in biological samples.\(^{139}\)

In contrast, the spectrum of PE 16:0/18:1 is more difficult to interpret. This is amazing, since PC as well as PE are both zwitterionic lipids with comparable properties. However, one must consider that PE possesses a \( \text{–NH}_3 \) group with exchangeable protons\(^{25}\); the peaks at \( m/z = 718.5 \) and 740.5 correspond to the \( H^+ \) and the \( Na^+ \) adduct of the PE as in the case of PC. In contrast, the peak at \( m/z = 762.5 \) corresponds to an exchange of one \( H^+ \) by \( Na^+ \), i.e., this peak can be assigned to \( PE - H^+ + 2Na^+ \). Additionally, in contrast with PC, the PE has a higher tendency to lose its polar head group, and this results in the peak at \( m/z = 577.5 \). The same fragment (but with lower intensity) is also detected in the case of PS 16:0/18:1 that possesses the same fatty acyl composition as the PE. In the case of the PS, different adducts \( (m/z = 784.6, 806.6, \) and 828.6) are also detected. This is not surprising, as the PS is an acidic PL and there are different possibilities to compensate its negative charge to obtain a singly charged positive ion. A survey of the mass spectrometric properties of different lipid classes was recently published\(^{25}\) and their tendency to give fragment ions was discussed.\(^{140}\) It is notable that the different adducts of a certain lipid have different tendencies to give fragment ions.\(^{42}\) For instance, it was shown in the example of PC that the \( Na^+ \) adducts give much more fragment ions and are, therefore, much more useful for structural investigations than the corresponding \( H^+ \) adducts that are dominated by the loss of the polar headgroup.\(^{138}\) A similar investigation is also available for the fragmentation behavior of PE.\(^{141}\)

Surprisingly, the triolein does not give a mixture of \( H^+ \) and \( Na^+ \) adducts, but the \( Na^+ \) adduct is exclusively detected at \( m/z = 907.8 \). Although this behavior of triacylglycerols (as well as DAGs)\(^{56}\) is well known,\(^{142}\) only very recently, a potential explanation has been provided.\(^{143}\) It has been suggested that the \( H^+ \) adducts are generated in similar amounts as the \( Na^+ \) adducts. However, their stability is much lower in comparison to the \( Na^+ \) adducts. Accordingly, the \( H^+ \) adducts do not “survive” the TOF distance and yield the fragment ion clearly detectable at \( m/z = 603.5 \) corresponding to the loss of one acyl residue. Consequently, to decrease the yield of fragment ions, it has also been suggested to perform the sample preparation under alkaline conditions, where the yield of \( H^+ \) adducts is much lower.\(^{143}\)

Generally, the yield of alkali adducts depends strongly on the alkali ion content of the sample. This means, for example, that \( Na^+ \) adducts may be replaced by \( K^+ \) adducts when an excess of \( K^+ \) is added to the lipid solution.\(^{24}\) This may also be useful when problems with overlapping peaks \((H^+, Na^+, \) and differences in acyl compositions) have to be solved, although, in that case, the use of \( Cs^+ \) seems still more advisable.\(^{144}\)

Generally, the negative ion mode is less frequently used for the characterization of lipids. There are two reasons: (i) not all lipids are detectable as negative ions and (ii) the matrix (DHB is most often used for lipids)\(^{25}\) provides more intense signals in comparison with the positive ion spectra.\(^{58}\) Accordingly, because the triolein does not possess acidic groups, it is not detectable as negative ion. The detected signals at \( m/z = 681 \) and 857 are caused by oligomerization of the applied DHB matrix.\(^{122}\) Of course, PS \( (m/z = 760.6) \) and PE \( (m/z = 716.5) \) can also be detected as negative ions because of their exchangeable protons, respectively. Surprisingly, there are additional peaks at higher masses, for instance, at \( m/z = 892.5 \) in the case of the PE.\(^{141}\) This signal is caused by a cluster ion between the lipid \((detected as negative ion at m/z = 716.5)\) and the applied DHB matrix \((atomic mass of the corresponding sodium salt: 176)\). Although the formation of matrix ion clusters was not yet comprehensively studied, it is of interest to note that such clusters with PC enable the detection of PC as negative ion at \( m/z = 912.6 \).\(^{145}\) This cluster ion formation seems a unique feature of DHB, because by using other matrix compounds as \( 2,4,6\)-trihydroxyacetophenone\(^{146}\) or para-nitroaniline (PNA),\(^{147}\) matrix lipid clusters could not be observed.

Generally, the presence of PC in lipid mixtures in similar amounts as other lipids causes problems, as PC is very sensitively detectable as positive ion because of the permanent positive charge of its choline headgroup. Therefore, its presence may lead to the suppression of the signals of further lipid classes.\(^{122}\) Unfortunately, this does not only hold for the positive ion detection mode but the detection of negatively charged lipids as negative ions is also influenced by the presence of PC.\(^{148}\) A detailed investigation of the detection limits of different important PLs was reported by Gellermann et al.\(^{149}\)

Although the preferred detection of lipid classes with quaternary ammonia groups (PC, sphingomyelin, and the corresponding lysolipids) may also be regarded as an advantage because the spectra are significantly simplified if only selected lipid classes are detected, this is simultaneously a disadvantage: previous separation into the individual lipid classes is required if a more detailed lipid analysis is to be performed. As thin-layer...
chromatography (TLC)\textsuperscript{(150)} is an established analytical tool in lipid research, there is an increasing interest in the direct coupling between MALDI and TLC, enabling the direct detection of PLs on the TLC plate subsequent to separation. Such approaches were already established for glycolipids,\textsuperscript{(151)} but only minor attempts were made to develop a suitable method of PL analysis by direct MALDI/TLC coupling.

Two different approaches are so far available: the first one used a home-built orthogonal MALDI/TOF device with an IR laser\textsuperscript{(152)} and glycerol as matrix, whereas the second approach applied a commercially available device equipped with a UV laser.\textsuperscript{(153)} Both reports indicated comparable sensitivities and resolutions. The use of the dye primuline is recommended for staining the individual lipids on the TLC plates because this dye does not bind covalently to lipids and, therefore, does not alter their molecular weights.\textsuperscript{(154)}

Quantitative analysis of MALDI/TOF mass spectra of lipids can be performed by three different methods:\textsuperscript{(25)} (i) by the use of a known internal standard, (ii) by the comparison of the peak intensity of the analyte with a known matrix peak, or (iii) by using the S/N ratio.\textsuperscript{(155)} Method (i) seems most suitable for DAG\textsuperscript{(56)} and PC analysis, whereas (ii) has so far only been used for apolar lipids, especially triacylglycerols.\textsuperscript{(142)} Finally, method (iii) is suitable for the analysis of acidic PLs, e.g. phosphoinositides,\textsuperscript{(148)} and lysophospholipids.\textsuperscript{(155)} Nevertheless, the determination of absolute amounts of different PL classes in mixtures by MALDI/TOF MS is still difficult and spectroscopic techniques as $^{31}$P NMR seem superior for that application.\textsuperscript{(156)}

There are obviously several important applications of lipid analysis by MALDI/TOF MS. First, the rough lipid composition of an unknown sample can be easily and quickly estimated. To achieve this, the sample is extracted by known procedures with mixtures of methanol and chloroform, plus hydrochloric acid, if more polar lipids have to be investigated.\textsuperscript{(157)} After separation of the organic and the aqueous layer, the chloroform layer can be immediately applied to the MALDI target without any further purification, since common impurities like salts and buffer components remain in the aqueous layer. However, the organic layer should be washed several times with distilled water.\textsuperscript{(66)}

In Figure 14, this technique was applied to obtain PL profiles of different cell lines (murine stem cells, astroglia, and rat hepatocytes) and one selected tissue (human liver). Both, positive (A) and negative (B) ion spectra are shown and it is obvious that a clear differentiation of all samples can be easily made at the first glance.

As already indicated above, the detection of PE in mixtures is a major problem as this PL is only scarcely detectable as negative ion,\textsuperscript{(141)} but is suppressed in the positive ion mode by lipids with quaternary ammonia groups that are more sensitively detectable.\textsuperscript{(122)} To be

\caption{Positive (A) and negative (B) ion MALDI-TOF mass spectra of organic extracts of murine stem cells (a), astroglia (b), rat hepatocytes (c), and human liver (d). All spectra were recorded with para-nitroaniline (PNA) as matrix. To minimize peak overlap between H\textsuperscript{+} and Na\textsuperscript{+} adducts on the one hand, and differences in fatty acyl compositions on the other, all solutions were saturated with CsCl.\textsuperscript{(144)}}
\end{figure}
able to detect PE in the negative ion mode and to avoid suppression effects of further negatively charged PL (e.g., phosphatidylinositol (PI) at \( m/z = 885.6 \)) or PL with quaternary ammonia groups, PNA was used as matrix.\(^{147}\) Furthermore, for the detection of positive ions, an excess of CsCl was added to the matrix solution to assign peaks unequivocally and to avoid overlap between \( H^+ \), \( Na^+ \), and \( K^+ \) adducts of lipids with different acyl compositions.\(^{144}\)

The mass spectra of the murine stem cells indicate the most pronounced diversity of PLs, particularly in the positive ion mode. Furthermore, stem cells contain high amounts of ether-linked PL (cf. the peaks at \( m/z = 878.5, 900.5 \), and 928.5) and highly unsaturated acyl chain residues (the peak at \( m/z = 942.5 \), for instance, represents PC 18:0/20:4). It is obvious that such compounds are nearly completely absent in the spectrum of the astroglia (Figure 14b). In contrast, the mass spectrum of the astroglia extract contains a significant concentration of PC 16:0/16:0 (\( m/z = 866.5 \)) that is rather typical of this cell line and represents a completely saturated lipid species. In the same way, the positive ion spectra of hepatocytes (Figure 14c) and the human liver extract (Figure 14d) can be easily differentiated. It is also obvious that the negative ion spectra allow a very fast estimation of the PE content: for instance, astroglia (Figure 14c) have only a very small PE content, whereas the liver (Figure 14d) and the stem cells (Figure 14a) possess a significant portion of PE, particularly PC 18:0/20:4 (\( m/z = 766.5 \)).

Although from this simple approach only a limited extent of information can be obtained, this type of analysis can be performed within a few minutes and, therefore, information on crude sample composition can be obtained in a very fast and convenient way. Many further cell and tissue extracts were investigated in this way, including granulocytes,\(^{24}\) human spermatozoa,\(^{158}\) animal spermatozoa (bull),\(^{159}\) and synovial fluid as well as serum\(^{160}\) from patients suffering from rheumatoid arthritis. A small textbook with the molecular weights of many relevant lipid classes and selected mass spectrometric properties of lipids is also available.\(^{161}\)

Finally, it should also be noted that MALDI/TOF MS analysis is not limited to organic extracts, but tissue slices may be also directly analyzed. For instance, Jones et al. have shown by analyzing different tissue sections of mouse brain, heart, and liver by MALDI Fourier-transform mass spectrometry (FTMS) that the quantitative data on lipid composition are superior in comparison to chromatographic reference data and provide higher accuracy.\(^{162}\) Although reports on “whole cell” lipid analysis are also available,\(^{163}\) there is so far only a single paper dealing with “whole animal” analysis.\(^{164}\) Daphnia Galatea with a diameter of a few millimeters were analyzed by MALDI/TOF MS by placing the animals directly onto the sample plate.\(^{164}\) Although reasonable spectra could be recorded allowing the assignment of many lipids, a rather poor S/N ratio was obtained because of poor sample purity.

Another important application of lipid analysis by MALDI/TOF MS is the examination of reactions accompanied by lipid peroxidation, which was primarily performed by ESI in the past.\(^{165,166}\) It is well known that lipids containing double bonds react quickly with “ROS” like hypochlorite\(^{167}\) or hydroxyl radicals (\( HO^+ \)) under the formation of (to a greater or lesser extent) characteristic products.\(^{168}\)

To investigate such reactions, MALDI/TOF analysis is very useful, because it can provide fast information on molecular weights and quantitative information on the extent of lipid modification.\(^{169}\) As a typical example, the conversion of PC 18:0/18:1 (its monoisotopic mass is 785.6) to the corresponding chlorohydrine under the influence of the HOCl-generating system myeloperoxidase–\(H_2O_2\)–\(Cl^− \) is shown (Figure 15). Myeloperoxidase (MPO) is the enzyme that catalyzes the generation of HOCl from \( H_2O_2 \) and \( Cl^- \) under inflammatory in vivo conditions.

It is evident that chlorohydrine formation\(^{169}\) can be easily followed by the increase of the peak at \( m/z = 840.6 \), which corresponds exactly to the molecular mass of the product expected upon the addition of hypochlorous acid to PC 18:0/18:1 (788.6 + 52 (HOCl)), if only the main abundant isotope of chlorine (\( ^{35}Cl \)) is used for the calculation.\(^{166}\) As expected, the corresponding \( Na^+ \) adduct is also detectable at \( m/z = 862.5 \). Further studies have also provided evidence that besides the chlorohydrines, LPC (lacking the unsaturated fatty acyl residue) is also generated by the reaction of PC with HOCl.\(^{170}\) However, the content of double bonds in the unsaturated fatty acyl residue seems to determine the yield of LPC: docosahexaenoyl residues (22:6) provide the most pronounced LPC generation, whereas oleoyl (18:1) residues provide only small amounts of LPC.\(^{170}\) Similar studies were also performed with plasmalogens that can – despite their rather labile alkenyl ether group – also easily be characterized by MALDI-TOF MS.\(^{171}\) It must be stressed, however, that the addition of acid (to enhance the yield of \( H^+ \) adducts) to the matrix must be strictly avoided, as plasmalogens are extremely sensitive to even traces of acids and decompose under the generation of LPC.\(^{159}\)

The very last comment on the analysis of lipids seems trivial, but neglecting this fact may give rise to a number of serious problems. This problem concerns details of the handling of the lipid samples. Lipid analysis usually requires the use of chloroform as solvent. Compared with most other widely used solvents, CHCl\(_3\) is a rather aggressive chemical that reacts with many
substances, including polymers. Therefore, it is strongly recommended to avoid any plastic material and to use exclusively glassware as reaction vessels. Additionally, glass syringes instead of plastic pipette tips, should be used. Figure 16 shows the MALDI/TOF (positive ion) mass spectra of CHCl₃ in which colored pipette tips had been stored for a few minutes.

The yellow pipette tip particularly (trace in Figure 16a) results in a number of impurities; these most likely correspond to the plasticizers in the material of the pipette tip. This fact should be carefully taken into account even if the molecular weights of the impurities do not fall into the range of the substances of interest. Since such plasticizers give a strong signal, particularly for the positive ion spectra, the intensity of the peaks of interest is considerably diminished.¹⁶⁶

6.5 Other Compounds

Some studies have examined the feasibility of MS for the investigation of nucleic acids,¹⁷² especially of smaller oligomeric units of ribonucleic acid (RNA).¹⁷³ These

compounds are rather difficult to analyze because they are characterized by a significant negative charge density caused by their phosphate residues. Therefore, low ion yields, fragmentation, and signal heterogeneity due to multiple cationization of the phosphate backbone are the main problems that need to be solved for successful performance. Although there are an increasing number of reports on this topic, its comprehensive treatment is outside the scope of this article.

Many studies available so far have used IR lasers as the ionization process by IR MALDI, which is known to be softer in comparison with UV MALDI. Using IR MALDI, DNA samples up to about 20 kDa have already been successfully analyzed. If UV MALDI is to be used, 3-HPA (3-hydroxy-picolinic acid) is the matrix of choice for DNA analysis. Surprisingly, the yield of positive and negative ions is comparable despite the considerable negative charge of DNA and RNA if 3-HPA is used. Nevertheless, sample preparation is still more important than in the case of other substances.

The MALDI/TOF analysis of other substance classes, for instance, carotenoids and analogous compounds, is described elsewhere.

### 6.6 Matrix-assisted Laser Desorption/Ionization Imaging

Over the past decade, a new analytical method “MALDI imaging” for examining biological samples and for visualizing analytical information has evolved. Clearly, this topic is out of the scope of the present article, but some comments seem necessary. For a more detailed review see the article by McDonnell and Heeren.

This new technique allows one to visualize the two-dimensional concentration profiles of defined biomolecules in or on the surface of biological samples, and it is expected to have a great impact on, for example, proteomics and metabolomics research in the future because of the available spatial resolution. One should, however, also note that such attempts have been performed since many years and are, therefore, not completely new. Even about 30 years ago, soon after powerful UV lasers first became commercially available, a new method was developed that permitted the mass spectrometric analysis of biological material, by using a highly focused laser beam. This “laser microprobe mass analysis” (“LAMMA”) technique already provided a spatial resolution of about 1 μm and not much progress was made as modern “MALDI imaging” devices (using nitrogen lasers with λ = 337 nm) could provide a resolution of only about 0.6 μm.

Although resolution seems quite limited in comparison with modern microscopic techniques, there are some recent encouraging applications. For instance, by imaging studies of human glioblastoma slices, it is possible to differentiate the tumor region from the ischemic and necrotic areas of the lesion on the basis of localization of different proteins. Very recently, “MALDI imaging” has also been successfully used to differentiate normal from the cancerous regions of man’s prostate by evaluating specific protein expression patterns. From these examples, it seems most likely that MALDI imaging will have a great future development.

### 7 QUALITY OF MASS SPECTRA

Usually, a “good” mass spectrum should exhibit an excellent mass resolution and a reasonable S/N. However, every user must decide what information is most important, since the resolution can be – at least to a certain extent – compromised for increased sensitivity and vice versa.

#### 7.1 Mass Resolution and Mass Accuracy

Reasonable mass resolution is often of particular importance, for example, to derive the elemental composition of an unknown compound. This is of particular relevance if the masses of peptides obtained by enzymatic hydrolysis of an unknown protein are assigned by database searching. If mass accuracy is relatively low, many potential peptide structures are obtained. The higher the mass accuracy, the lower is the number of “hits” in the database! Unfortunately, highly resolved mass spectra cannot be routinely acquired and require the use of sophisticated – and expensive – mass spectrometers, for instance, equipped with FTICR (Fourier transform ion cyclotron resonance). A more detailed description of this technique, which was recently reviewed, is outside the scope of this article.

Independent of the mass analyzer, each user of a mass spectrometer should be aware that the number of sampled data points is essential for high resolution. For example, if one wants to determine the mass of an unknown substance with an accuracy up to the third decimal point, at least 1000 data points/Da are required to achieve this. This means that for highly resolved mass spectra, the mass range must be minimized to obtain a sufficient number of data points. Commercially available MALDI/TOF devices provide mass resolutions of a few thousand (linear mode) up to about 20 000 in the reflectron mode under DE conditions. This indicates that mixtures of molecules with monoisotopic masses of 1000 and 1000.05 can still be resolved. The mass accuracy of many commercial devices is of the order of 20 ppm, i.e. if a compound with a mass of 1000 Da is investigated, the mass can be provided with 1000 ± 0.02. One should also note that changes of the
instrument settings to increase sensitivity (e.g., increasing the reflectron voltage) require new calibration of the instrument.\(^{25}\)

High mass resolution is not only important for the assignment of unknown peptides obtained by digestion of proteins, but is also typically required to determine whether a peak in a lipid spectrum, for example, corresponds to a K\(^+\) adduct (M + 39) or the Na\(^+\) adduct of the corresponding epoxide (M + 23 + 16). Since each possibility leads to slightly different masses (M + 38.9637 or M + 38.9847), exact mass determinations would allow the clear discrimination of both compounds.

However, the same information can also be obtained by a simple exchange experiment, using an excess of K\(^+\) or Cs\(^+\) \(^{144}\) instead of Na\(^+\).

### 7.2 Signal-to-noise Ratio

A reasonable S/N is highly desirable, for example, to identify low amounts of a certain compound of a mixture. Improving the S/N is a rather empirical process since it depends on a number of parameters that have to be carefully set. Such parameters include the analyte concentration, the matrix concentration, the analyte/matrix ratio, the applied laser intensity, the parameter setup, and so on. Here, for each substance and each sample, one has to find individually the best conditions. However, MALDI/TOF differs in a certain respect from most other analytical methods: an enhancement of the sample concentration does not necessarily increase the S/N. If the matrix/analyte ratio reaches a suboptimal level, the signal of the analyte is strongly suppressed.\(^{25}\)

### 7.3 Observed Fragmentations

In contrast with classical (EI) MS, where the inspection of fragmentation products mainly allows conclusions on chemical structure, in MALDI/TOF methodology the extent of fragmentation can be kept to a minimum and, usually, the (quasi) molecular ions provide the most important information. Therefore, some caution is needed not to obscure the molecular ion. In particular, the matrix should always be present in a large excess over the analyte to prevent a “direct hit” of the laser on the analyte, which would cause degradation of the sample.\(^{24}\)

It is also a widespread error that increased laser intensity leads to an improved S/N. In most cases, enhanced laser intensity is accompanied by a strong distortion of the baseline,\(^{56}\) which may prevent the observation of small quantities of analyte. Basically, using a different matrix and changing the pH of the applied solutions slightly may be sufficient to decrease the extent of fragment ion generation.

### 7.4 Troubleshooting

If the acquired mass spectra are not in accordance with the expected sample composition, or, even worse, no signal at all can be detected, there are a few general changes that can be tried.

For most mass spectra, the average of a fixed number of different laser shots is calculated. It is possible to observe the individual spectra and try to lead the laser beam to a “hot spot”. However, it may happen that all analyte on the sample plate has been spent (in some cases, the ablation from the sample plate can be seen). If this occurs (usually after about 30 “shots” on the same spot), the laser beam should be moved to a new point on the sample plate or more analyte should be applied to the sample plate.

A serious problem (especially in aqueous samples) is the disturbing effect of impurities. If the degree of contamination with salts, buffers, or detergents is not known, the following procedure is recommended. Prepare a comparably concentrated reference sample (e.g. 1 mg mL\(^{-1}\) serum albumin in pure water). This sample should give an intense, reproducible signal. Dilute the albumin sample with distilled water and with the sample of interest, and record the mass spectra. If the spectra differ markedly in signal intensity and mass resolution, the sample is contaminated and should be purified before further analysis. Dialysis, microdialysis, or applying ZipTips™ are often already sufficient to overcome this problem. Apolar impurities like detergents can be easily removed by binding to commercially available apolar beads. It is also important to note that the “limit of detection” (LOD) is mainly limited by the level of chemical background noise and hence, cannot be improved significantly by averaging over a larger number of laser exposures.\(^{152}\)

### 8 COMPARISON WITH OTHER MASS SPECTROMETRIC METHODS

Although, in the opinion of these authors, the MALDI/TOF technique is superior to other MS techniques in many respects, it must also be compared with other MS methods for advantages, drawbacks, and applicability (Table 1).

Ionization of the sample by EI\(^{2}\) provides well-reproducible and simple-to-quantify mass spectra, but also a high extent of fragmentation. This is the reason why the molecular ion is only rarely detected (or is very weak).\(^{3}\) Most ionization techniques also exhibit this problem and are, therefore, not suitable for the analysis of high-molecular-weight compounds exceeding masses of a few kilodaltons. However, EI is still the
ionization of choice for quantitative investigations, and gas chromatography/mass spectrometry (GC/MS) is still a very important method. The reason is that EI generates radical cations. The yield of these radical cations depends primarily on the available functional groups within the analyte. In contrast, using ionization methods that give “quasimolecular” ions under the addition of cations to the analyte, the ion yield is much more dependent on the acidity or basicity of the analyte. This is the reason why internal standards should always be used for quantitative investigations by MALDI or ESI MS.

Both MALDI and ESI represent “soft-ionization” techniques giving only very minor degradation of the sample, and both these techniques are further compared. ESI generally provides more accurate mass information on low-mass compounds than MALDI and can be very easily combined with chromatographic techniques. By comparison, MALDI is more sensitive in many cases, can also be applied to very large biomolecules (larger than 100 kDa as TOF detectors basically enable an unlimited mass range), and is relatively insensitive toward salt concentrations in the millimolar range. Additionally, MALDI yields simpler spectra, since ESI produces a number (20 or more) of molecular ions, from which the mass of the analyte can be calculated. The ESI process seems softer than MALDI and ESI has also the considerable advantage that the analyte is investigated in solution, whereas for MALDI cocrystallization with the matrix is required. Labile molecules may not survive this procedure and this is why the analysis of noncovalent complexes is still a domain of ESI MS.

Both methods, MALDI and ESI, often give complementary information. Therefore, it is more beneficial to ask “Can I use both methods to obtain an optimum of information?” rather than to ask “Which method should I use?”.

9 SUMMARY AND METHOD DEVELOPMENT

The most important fundamentals of MALDI/TOF MS have been described, and its applicability to the investigation of different selected substance classes has been discussed. The comparison between MALDI and ESI has been emphasized because these relatively new methods are both “soft-ionization” techniques that yield information mainly on the intact molecular ion. This makes both methods very suitable for the analysis of mixtures. However, it must be considered that ion yields may differ from compound to compound, and less sensitively detectable compounds may be suppressed by more sensitively detectable ones.

One of the most important applications of MALDI/TOF is protein analysis, very often in combination with other biochemical methods prior to MALDI analysis. Proteins with a molecular weight close to 1000 kDa have already been successfully characterized. Subsequent to an enzymatic digestion of the protein, MALDI is especially well suited for so-called peptide mapping. The high sensitivity and the adequate mass resolution of MALDI/TOF make it a strong competitor for classical electrophoresis. The most current trend in this field is automatization. Mass spectrometers will soon achieve complete, nearly fully automated, sequence analysis of proteins. However, a major drawback is the still relatively low reproducibility of MALDI/TOF mass spectra owing to the limited homogeneity of crystallization between the matrix and the analyte. Here, the search for further useful matrices is essential.

In comparison with protein analysis, there are by far fewer applications of MALDI/TOF for the analysis of carbohydrates and lipids. Whereas lipids can be very easily and accurately characterized, carbohydrates are still a major problem. Acidic carbohydrates, particularly, show a very weak tendency to desorb and are, therefore, very difficult to analyze. To solve these problems, some efforts are necessary, and the search for suitable matrices has to be continued. Further developments in MALDI/TOF MS will follow increasing knowledge of the matrix and its interaction with the analyte.

At present, a major drawback in the field of MALDI MS is the limited, quantitative analysis of MALDI/TOF mass spectra. Although there were some recent reports on this, one major problem is still the limited homogeneity of the cocrystals between matrix and analyte. Further experimental progress is expected in this area as this would be also important to establish MS imaging as a reliable diagnostic tool.

ACKNOWLEDGMENTS

The authors wish to thank all colleagues and friends who helped them in writing this article. We especially wish to thank Dr Holger Spalteholz, Dr Jacqueline Leßig, Dr Matthias Müller, and Ms Rosmarie Süß. The kind and helpful advice of Dr Suckau and Dr Schüenberg (Bruker Daltonics, Bremen) is also gratefully acknowledged.

This work was supported by the German Research Council (DFG Schi 476/5-1, Schi 476/7-1 as well as the former HBFG program enabling the purchase of a Bruker “Autoflex” device) and the Federal Ministry of Education and Research (Grant BMBF 0313836).

Nuclear Magnetic Resonance of Biomolecules

Jeremy N.S. Evans
Washington State University, Pullman, USA

1 INTRODUCTION
1.1 How Nuclear Magnetic Resonance is Used to Study Biomolecules

The methods of NMR spectroscopy have proved to be an essential analytical method for the determination of the structures of biomolecules, and in the study of biomolecular function. This article provides an overview of the principal NMR methods that can be employed in structure–function studies of biomolecules, with the main focus on structure determination. Many texts discuss these topics in greater detail than can be considered here.\(^{(1-10)}\)

1.2 Practical Considerations

The success or failure of any biomolecular NMR project is completely dependent upon the quality of spectra generated by the particular samples under study. For...
example, although it is generally true that proteins with $M_r > 50$ kDa are largely intractable projects by liquid-state NMR, there are examples of proteins with $M_r < 10$ kDa that give impossibly broad spectra, and proteins with $M_r > 60$ kDa that, with appropriate measures, give reasonably well-resolved spectra. Thus no NMR project should be ruled in or out without extensive preliminary tests of conditions to investigate whether the project is viable. In this sense, biomolecular NMR spectroscopy is similar to X-ray crystallography, where obtaining crystals is equivalent to getting a spectrum, and getting diffraction-quality crystals is equivalent to getting well-resolved spectra. Just as the X-ray crystallographer searches a wide variety of crystallization conditions, including testing temperature, pH, ionic strength, solvent and so on, so the NMR spectroscopist must carry out similar kinds of studies.

1.3 Instrumentation

For most biomolecular NMR studies, a high-field NMR spectrometer is necessary, at least 500 MHz (for $^1$H, 11.7 T) for liquids and 400 MHz (9.4 T) wide-bore (89 mm) for solids – bigger is generally better (although there are reasons for doing studies at particular field strengths, as discussed later). For a biomolecular liquid-state NMR structure determination, generally a 600 MHz (14 T) instrument is preferable, whereas for biomolecular solid-state NMR structure determination (although there are advantages in going to higher fields) there are also technical issues that presently limit the kinds of experiments possible. The highest commercially available field strength (in early 1999) is 800 MHz (18.8 T), although a 900 MHz (21.2 T) instrument is scheduled for completion by summer 2000. To date, 800 MHz has become the field strength of choice in leading protein NMR laboratories doing liquid-state NMR, and a number of solid-state NMR laboratories are also exploring this field strength in their work.

2 BIOMOLECULAR SPECTRAL ASSIGNMENTS

The first step in biomolecular NMR spectroscopy, in particular by $^1$H liquid-state NMR, is the assignment of the NMR spectrum. For this, a general strategy for identification and assignment of resonances is usually adopted, which employs a number of two-dimensional (2D) or higher (3D, four-dimensional (4D)) NMR experiments. Some of the basic experiments are discussed here, followed by an account of how they are employed in carrying out sequence-specific assignments. For large biomolecules these approaches fail and alternative methods are considered in section 2.3.3 for such situations. Once the assignments have been obtained, then this information can be used to solve the biomolecular structure (section 3) or used to interpret biochemical events (section 5.2).

2.1 Two-dimensional Nuclear Magnetic Resonance Experiments

2.1.1 Correlation Spectroscopy

The most important 2D NMR experiment is the correlation spectroscopy or COSY experiment, introduced by Jeener in 1971. The sequence consists of $90^\circ - t_1 - 90^\circ$ and, in the presence of homonuclear scalar $J$ coupling, it gives information about coupling networks. In a coupled system, the second pulse of the experiment causes magnetization that arose from one transition during $t_1$ to be redistributed amongst all the others with which it is associated. With this sequence of pulses, in the presence of coupling, magnetization evolves with different frequencies during the two time intervals because coherence is transferred between multiplets during the second pulse.

Another important variant on the basic COSY sequence is double-quantum-filtered correlation spectroscopy (i.e. DQFCOSY), in which an extra $\pi/2$ pulse is added immediately after the end of the COSY sequence (Equation 1):

$$\frac{\pi}{2} - t_1 - \frac{\pi}{2} - \Delta - \frac{\pi}{2} - t_2(\text{acquire})$$

where $\Delta$ is a short phase switching delay, and multiple quantum coherences that existed before the third pulse are converted back to observable magnetization. With a suitable choice of phase cycling, signals that have arisen from different orders of multiple quantum coherence can be separated out. For instance, double quantum coherence is twice as sensitive to phase changes in its excitation sequence as is single quantum coherence. Therefore by shifting the phase $\phi$ of the first two pulses (in general, all pulses before the coherence is created) by $90^\circ$, the phase of the detected signal which came via double quantum coherence is inverted. Inverting the receiver phase (i.e. subtracting the $90^\circ$ from the $0^\circ$ experiment) then selects the component which passed through double quantum coherence. To select $p$-quantum coherence, the rule is to step the phases of the excitation pulses through the sequence $0, 180/p, \ldots (2p-1) \times 180/p$, alternating the receiver phase for each scan. The advantages are considerable improvement in spectral simplification. Singlets are largely eliminated in DQFCOSY. Furthermore the diagonal and the cross-peaks are in pure absorption
phase, improving the resolution. The disadvantage is that DQF COSY is less sensitive by a factor of 2 than conventional COSY.

2.1.2 Total Correlation Spectroscopy

Total correlation spectroscopy (TOCSY) or its variant homonuclear Hartmann–Hahn (HOHAHA) spectroscopy is an experiment that relies on cross-polarization (CP) rather than coherence transfer, and whose pulse sequence is shown in Figure 1.

The spin-locking field causes cross-polarization, or an oscillatory exchange of spin-locked magnetization between two spins, provided that the effective local RF fields experienced by the two spins are identical. This causes the spins to become temporarily equivalent. The spin-lock sequences are termed “isotropic mixing” (with no effective field) or “Hartmann–Hahn mixing” (with an effective field, i.e. this is the HOHAHA experiment). Isotropic mixing leads to spectra with mixed phases (phase modulated), whereas in Hartmann–Hahn mixing, pure phases are obtained. For a simple two-spin system, complete exchange of magnetization occurs for contact times (or spin-lock mixing times) equal to 1/(2J), where J is the two-spin scalar coupling constant. For biological macromolecules, which involve large spin systems, there is no simple analytical solution, and in practice spectra are usually obtained with a variety of spin-lock mixing times.

2.1.3 Heteronuclear Single Quantum Coherence and Heteronuclear Multiple Quantum Coherence

One of the most important experiments in biomolecular NMR is the heteronuclear single quantum coherence (HSQC) correlation experiment, and its more general form, the heteronuclear multiple quantum coherence (HMOC) (11) experiment (sometimes referred to as the “forbidden echo” experiment) (12–14). These experiments exploit the intrinsically greater sensitivity of protons to indirectly detect a heteronucleus such as $^{13}$C and $^{15}$N. The basic HMOC pulse sequence is shown in Figure 2.

![Figure 1](Image 203x138 to 252x186)

**Figure 1** The TOCSY pulse sequence. (Adapted from ref. 8 with permission.)

![Figure 2](Image 504x151 to 546x192)

**Figure 2** The basic HMQC pulse sequence. The delay $\Delta$ is usually set to $\sim$20% less than 1/4(JIS). (Adapted from ref. 8 with permission.)

In terms of product operators, a heteronuclear spin system IS is represented by Equation (2),

$$I_z \xrightarrow{A,B} -2I_xS_y \xrightarrow{t_1} -2I_xS_y \cos w_{ST_1} \xrightarrow{B} -I_y \cos w_{ST_1}$$

where A and B are operators representing the effect of the pulse sequence before and after the $t_1$ period, respectively, and the pulse phases are assumed to be $+\pi$. Equation (2) indicates that the proton signal ($I_y$) which is detected will be in-phase and amplitude modulated by $w_{ST}$, giving rise to a single absorption line in the 2D spectrum. Considering a second coupled proton $M$, then the effect of the small homonuclear coupling $J_{SM}$ during the short delays $\Delta$ can be neglected. During $t_1$, dephasing caused by $J_{SM}$ coupling is refocused by the 180° pulse. However, the effect of any $J_{SM}$ coupling is not refocused, because both coupled nuclei are influenced by the 180° pulse. Therefore the effect of the pulse sequence is given by Equation (3):

$$I_z \xrightarrow{A,B} -I_y \cos \pi J_{SM}t_1 \cos w_{ST_1} + 2I_xM_z \sin \pi J_{SM}t_1 \cos w_{ST_1}$$

The detected signal will consist of four multiplet components at $w_{ST} \pm \pi J_{SM}$ and $w_{ST} \pm \pi J_{SM}$, and will contain both in-phase absorptive ($I_y$) and antiphase dispersive ($2I_xM_z$) components.

The pulse sequence of the HSQC experiment is shown in Figure 3.

![Figure 3](Image 507x672 to 547x711)

**Figure 3** The HSQC pulse sequence. (Adapted from ref. 8 with permission.)
This is a variation on an experiment introduced by Bodenhausen and Ruben\cite{15} and employs two insensitive nuclear enhancement by polarization transfer (INEPT)-type\cite{16,17} transfers to transfer magnetization from the protons to the low-$J$ nucleus and back to the protons. The INEPT sequence transfers $I_{\text{spin}}$ (e.g. $^1\text{H}$) magnetization into antiphase $S$-spin magnetization. Decoupling the $I$ spin during $t_1$ is accomplished by application of a $180^\circ$ pulse at the midpoint of $t_1$. A subsequent INEPT transfer reconverts the transverse $S$ magnetization into observable $I$ magnetization. Equation (4) expresses this in terms of product operators:

$$I_z \xrightarrow{\text{INEPT}} -2I_zS_y \xrightarrow{t_1} -2I_zS_y \cos w_{3t_1}$$

$$\text{reverse INEPT} \quad \xrightarrow{-I_z \cos w_{3t_1}} \quad (4)$$

where for clarity only those terms that contribute to the final spectrum are retained, and the phase of the pulses are given that correspond to the first step in the phase cycle. Pure absorptive lineshapes are obtained. Furthermore the linewidth is narrower than with the HMQC experiment, because it is not affected by homonuclear or heteronuclear $J$ couplings and determined by the average relaxation rates of $S_x$ and $I_x$. There are a number of advantages that HSQC has over HMQC, principally in terms of sensitivity.\cite{18–20}

It is for this reason that HSQC has emerged as the gold standard for determining the viability of a biomolecular NMR project. A $^1\text{H}-^1\text{N}$ HSQC is routinely obtained on a protein to establish whether a particular sample gives well-resolved and well-dispersed spectra.

### 2.1.4 Nuclear Overhauser Effect Spectroscopy

The 2D experiment that permits the detection of the nuclear Overhauser effect (NOE) is the NOESY (nuclear Overhauser effect spectroscopy) pulse sequence given in Equation (5):

$$\frac{\pi}{2} \phi \quad -t_1 \quad \frac{\pi}{2} \phi \quad -\tau_m \quad \frac{\pi}{2} \phi \quad \text{Acquire}(t_2) \quad (5)$$

The first $90^\circ\phi$ pulse creates transverse $xy$ magnetization, and the spins now precess during $t_1$ as in the COSY sequence. The second $90^\circ\phi$ pulse rotates components of the magnetization along the $-z$ axis. During the subsequent mixing period $\tau_m$, $z$-magnetization components exchange under the influence of cross-relaxation. The transverse components are not required and are removed by phase cycling. The magnetization vectors therefore have a component in the $z$ direction only after these procedures. Finally, a third $90^\circ\phi$ pulse regenerates observable magnetization. If this sequence is repeated for a larger value of $t_1$, the magnetization vectors would dephase further, and a smaller $-z$ component is thus created, which would pass through zero and become positive for increasing values of $t_1$. The changes are “read” by the final $90^\circ$ pulse. The cross-peaks are generated from the magnetization transfer (cross-relaxation) between two spins.

Note that in any practical application, a variety of cross-peaks can be generated by mechanisms other than cross-relaxation, and these cause confusion in interpreting the data. In addition, chemical exchange cross-peaks occur (which can be valuable if chemical exchange is known to be taking place), but can be a source of undesirable confusion. Furthermore, in a weakly coupled system the cross-relaxation pathways arising from coherence transfer between $I$-coupled spins has to be considered. By analogy with the COSY pulse sequence, the system remains the same until after the second $90^\circ\phi$ pulse, when the density operator takes the form of Equation (6):

$$\sigma_3 = [-I_z \cos w_{3t_1} + I_z \sin w_{3t_1} - S_z \cos w_{3t_1} + S_z \sin w_{3t_1} \cos \pi J_{IS} - [-2I_zS_z \cos w_{3t_1} + 2I_zS_z \times \cos w_{3t_1} - 2I_zS_z \sin w_{3t_1} + 2I_zS_z \sin w_{3t_1} \sin \pi J_{IS}]] \sin \pi J_{IS} \sin w_{3t_1} + 2I_zS_z \sin w_{3t_1} \sin \pi J_{IS} \quad (6)$$

The terms $2I_zS_z$ and $2I_zS_z$ consist of a superposition of double- and zero-quantum coherences, which can be shown by expanding $\sigma_3$ (Equation 7):

$$\sigma_3 = [-I_z \cos w_{3t_1} + I_z \sin w_{3t_1} - S_z \cos w_{3t_1} + S_z \sin w_{3t_1} \cos \pi J_{IS} - \frac{1}{2}(2I_zS_z + 2I_zS_z)[^1]$$

$$- (2I_zS_z + 2I_zS_z)[^3] \cos w_{3t_1} + \frac{1}{2}(2I_zS_z + 2I_zS_z)[^3]$$

$$+ (2I_zS_z + 2I_zS_z)[^4] \cos w_{3t_1} + 2I_zS_z \sin w_{3t_1} + 2I_zS_z \sin w_{3t_1} \sin \pi J_{IS} \quad (7)$$

where the terms labeled $[^1]$ and $[^3]$ represent double quantum coherence, and those labeled $[^2]$ and $[^4]$ represent zero quantum coherence. As we are only interested in longitudinal magnetization components during the mixing period $\tau_m$, it is necessary to remove all the components except $-I_z \cos w_{3t_1}$ and $-S_z \cos w_{3t_1}$. In order to do this, we can phase cycle the first two pulses by $90^\circ\phi$ each: $xx$, $yy$, $-x$, $-x$, $-y$, and $-y$, and add each separate response, then this will cancel coherences of order $1, 2, 3, 5, \ldots$ and leave the zero quantum coherences. Thus at the beginning of the mixing period Equation (8) holds:

$$\sigma_3 = (-I_z \cos w_{3t_1} - S_z \cos w_{3t_1}) \cos \pi J_{IS}$$

$$+ (I_zS_z - I_zS_z)[\cos w_{3t_1} - \cos w_{3t_1}] \sin \pi J_{IS} \quad (8)$$
The zero quantum term \((I_sS_x - I_xS_y)\) evolves in a way that depends on the difference in the chemical shifts, and the longitudinal \((-I_z\) terms mix under the effects of cross-relaxation. After the final 90° pulse, the observable magnetization is given by Equation (9):

\[
\sigma^{\text{obs}}_m = [I_xa_{IM} \cos w_I t_1 + S_ya_{IS} \cos w_I t_1 + I_xa_{SI} \cos w_S t_1 + S_ya_{SI} \cos w_S t_1] \cos \pi J_{IST} t_1 + (I_xS_x - I_xS_y) \times \cos(w_I - w_S) \tau_m (\cos w_I t_1 - \cos w_S t_1) \sin \pi J_{IST} t_1
\]

(9)

The terms in \(\sigma_m\) represent diagonal peaks proportional to the mixing coefficients \(a_{IM}\) and \(a_{IS}\), and NOE cross-peaks proportional to \(a_{SI}\) and \(a_{IS}\). These are all in phase with respect to \(J_{IS}\). Also, there are diagonal and cross-peaks that are antiphase with respect to \(J_{IS}\). These are the \(J\) cross-peaks derived from zero quantum coherence that cannot be removed by phase cycling, and have to be eliminated by other methods (e.g. random incremental variation of \(\tau_m\)).

For a three-spin system, \(I, S,\) and \(M\), the I-spin diagonal peak intensity governed by \(a_{II}\) decays with increasing \(\tau_m\), whereas the \(S\)- and \(M\)-spin cross-peak intensities, generated by \(a_{IS}\) and \(a_{IM}\), increase before decaying with increasing \(\tau_m\). The importance of the time development of cross-peak intensities is that the initial build-up rates of the \(S\)- and \(M\)-spin cross-peaks (i.e. at \(\tau_m = 0\)) are proportional to \(\sigma_{IS}\) and \(\sigma_{IM}\). If, therefore, \(a_{IM}\) corresponds to a known fixed internuclear distance \(r_{IM}\), \(r_{IS}\) can be calculated from the \(r^{-6}\) dependence of \(\sigma\) (Equation 10):

\[
\frac{r_{IM}}{r_{IS}} = \frac{\sigma_{IS}}{\sigma_{IM}} \frac{1}{6}
\]

(10)

This is the principal method by which quantitative distance information is obtained in biomolecular NMR. A series of NOESY spectra is recorded as a function of mixing time in order to generate experimental plots similar to those obtained experimentally, as shown above. Alternatively, if one can be certain that the measured cross-peak intensities in a single NOESY experiment for a given mixing time were developed within the initial rate approximation, then quantitative distance information can be obtained with good accuracy by measurement of relative cross-peak intensities rather than initial rates (Equation 11):

\[
\frac{r_{IM}}{r_{IS}} = \frac{a_{IS}}{a_{IM}} \frac{1}{6}
\]

(11)

Note that this is true for the initial rate approximation only.

### 2.2 Three-dimensional and Four-dimensional Experiments

One of the problems with \(^1\text{H}\) NOESY NMR of proteins is that all the NOEs must be resolved. This becomes increasingly difficult with higher-molecular-weight proteins. To solve this problem, a whole family of pulse sequences have been introduced that involve three time variables rather than two, so that 3D Fourier transformation leads to a cube rather than a contour map. They involve using an isotopic label for indirect detection via HMQC/HSQC methods in combination with a type of COSY or NOESY sequence. Almost all of these 3D (and 4D) pulse sequences rely on heteronuclear and homonuclear couplings for correlating resonances from

![Figure 4](image_url)
one residue to the next, in for example an oligopeptide, oligonucleotide or oligosaccharide. Rather than provide a detailed description of all the pulse sequences used in modern biomolecular NMR, they are summarized in Figure 4. The $J$ couplings involved, and the correlations which each sequence can obtain, are illustrated in Figure 5 for a dipeptide fragment.

The majority of experiments involve a heteronucleus, and coherence is transferred from one nucleus to the next, usually ending up on $^1$H, which is then detected. Such coherence transfers are achieved using INEPT and related approaches. As is clear from Figure 5, the amide protons are correlated with the $\alpha$ carbons using the HNCA$^{(21-25)}$ and HN(CO)CA$^{(25,26)}$ experiments. The HNCA provides intrar residue couplings ($H^N\overset{\alpha}{H}\overset{\alpha}{C} (C_{i-1})$), whereas the HN(CO)CA provides exclusively interresidue correlations ($H^N\overset{\alpha}{H}\overset{\alpha}{C} (C_{i-1})$). The latter experiment is more sensitive and is complementary to the HNCA experiment. The amide protons are correlated with the $\alpha$ protons using the H(CA)NNH, HN(CA)H, HN(CA)HA, and HN(COCA)HA experiments. The H(CA)NNH$^{(27,28)}$ HN(CA)H$^{(29)}$ and HN(CA)HA$^{(30)}$ experiments all provide the same correlations ($H^N\overset{\alpha}{H}\overset{\alpha}{H} (H^N\overset{\alpha}{H}_{i-1})$). The HN(CA)NNH situation is not very sensitive for $M_i > 20$ kDa, and HN(CA)HA is significantly more sensitive and has been used to assign a 27-kDa protein.$^{(31)}$ The HN(CA)H has even more improved sensitivity, particularly for larger proteins (>30 kDa). The HN(COCA)HA$^{(32)}$ correlates $H^N\overset{\alpha}{H}\overset{\alpha}{H} (H^N\overset{\alpha}{H}_{i-1}$) and is analogous to the HN(CO)CA, providing exclusively interresidue correlations, and is therefore complementary.

**Figure 5** Some examples of 3D and 4D pulse sequences. These are presented in their simplest form, without pulse field gradients or constant-time implementations. (Adapted from ref. 8 with permission.)
to the H(CA)NNH, HN(CA)H, and HN(CA)HA experiments. The amide protons are correlated with the carbonyl carbons using the HNCO and HN(CA)CO experiments. The HNCO(21,22,33,34) experiment correlates H$_N$ N$_H$ C$^a_{i-1}$, and its high sensitivity makes it attractive in assignment strategies. The HN(CA)CO(25,35) provides intraresidue and some weaker interresidue correlations, but is much less sensitive, and therefore complementary to the HNCO experiment. The amide protons are correlated with the $\alpha$ and $\beta$ protons using the CBCA(CO)NH, CBCANH, HNCABC, HBHA(CBCACO)NH, and HBHA(CBCA)NH experiments. The CBCA(CO)NH(33,36) experiment correlates H$_N$ N$_H$ C$^\alpha_{i-1}$, and is an extension of the HN(CA)CO experiment, as it correlates both the C$^\beta$ and C$^\gamma$ chemical shifts with the amide from the previous residue. The CBCANH(37) experiment correlates H$_N$ N$_H$ C$^\alpha_{i-1}$ (C$^\beta_{i-1}$), and is an extension of the HNCA experiment, providing mainly intraresidue correlations, but with some interresidue correlations. Although in principle this one experiment can provide complete assignments for C$^\beta$, C$^\gamma$, 15N, and H$^N$ resonances, like the HNCA experiment, the sensitivity is limited, and it is mainly useful for smaller proteins ($M_t < 20$ kDa). The HNCABC(33,38) experiment provides the same information as the CBCANH, but is more sensitive. By using these experiments in conjunction with the HBHA(CBCACO)NH(39) (H$_N$ N$_H$ $\alpha^a_{i-1}$) and the HBHA(CBCA)NH(40) (H$_N^i$ N$_H^i$ $\alpha^b_{i-1}$) experiments, the assignment can be extended to the carbon-attached protons as well. In all these experiments, both the $\alpha$ and $\beta$ correlations appear in the same dimension.

The HCA(CO)N(21,22,41–43) experiment (H$_N^i$ C$^\gamma_{i-1}$ C$^\gamma_{i}$) and the HCA(CO)NH(21,22,41) experiment (H$_N^i$ C$^\gamma_{i-1}$ N$_H^i$) are both usually acquired with a sample in D$_2$O, in order to allow observation of those $\alpha$ protons otherwise obscured by the water resonance. This has the disadvantage of requiring two different samples in D$_2$O, in which small differences in preparation conditions can lead to differences in chemical shifts, and the presence of the deuterium leads to isotope shifts. However, the HCA(CO)N is more sensitive than other experiments such as the HN(CA)HA. Also, the HCA(CO)NH is useful for identifying residues preceding proline residues. There are also several other 3D sequences that have been proposed, such as the HN(CA)NNH(44) (H$_N^i$ N$_H^i$ N$_H^{i+1}$), H(NCA)NNH(44) (H$_N^i$ N$_H^i$ N$_H^{i+1}$), H(NC)CACO(45) (H$_N^i$ C$^\gamma_{i}$ C$^\gamma_{i}$), and HA(CANH)N(46) (H$_N^i$[N$_H^i$ + C$^\gamma_{i}$])H$_N^i$). These have not been as widely used in protein assignment strategies. Finally there is also the HCAOCANH (H$_N^i$ N$_H^{i+1}$ C$^\gamma_{i}$) experiment (47) which appears to be gaining in popularity.

The most common experiments for side-chain assignment are the HCCH COSY(48) and the HCCH TOCSY. These provide essentially the same information (H$_N^i$ C$^\gamma_{i}$ C$^\gamma_{i}$ with C$^\delta$ and C$^\omega$ being one bond apart) as the 2D COSY/TOCSY experiments, except that the COSY/TOCSY transfer is between carbon rather than proton nuclei. The third dimension correlates the shifts of the 13C nuclei attached to the protons on the diagonal which reduces the overlap. However, one disadvantage is that they are generally acquired with the sample dissolved in D$_2$O. One way round this is the HNCH(CO)TOCSY(52) experiment, which correlates the amide nitrogens, the $\alpha$ carbons, and the side-chain protons on a sample in H$_2$O. Alternatively, there are the C(CO)NH (H$_N^i$ N$_H^i$ C$^{\gamma+2}_{i-1}$) and H(CO)NNH (H$_N^i$ N$_H^i$ H$^\gamma_{i-1}$) experiments, which are both more sensitive.

There are a number of 4D experiments, although they all suffer from poor sensitivity. It is a necessity that 4D experiments use pulsed field gradients for coherence selection (54–56) with a minimum of phase cycling. They have been used as the only source of backbone assignments. The HCANNH (H$_N^i$ N$_H^i$ H$^\gamma_{i-1}$) and HCA(CO)NNH (H$_N^i$ N$_H^i$ H$^\gamma_{i-1} C^\gamma_{i-1}$) experiments are complementary, and can provide complete sequential assignments for all the backbone atoms apart from the carbonyl carbons. The HCANNH experiment gives intraresidue correlations and a few interresidue correlations; the HCA(CO)NNH gives exclusively interresidue correlations. Improved constant-time versions have also been introduced. The HNCAHA and HN(CO)CAHA experiments(60,61) together provide the correlations, but use different pulse sequences. In general the HCANNH is preferable for small proteins, whereas the HNCAHA is more sensitive for proteins with $M_t > 20$ kDa. The HCC(CO)NNH(62) experiment (H$_N^i$ N$_H^i$ C$^{\gamma+2}_{i-1}$ H$^\gamma_{i-1}$) is based on the HCA(CO)NNH and allows the assignment of the side-chain as well as the $\alpha$ nuclei.

The use of these experiments in carrying out sequential assignments is outlined in the next section.

### 2.3 Sequence-specific Assignments

#### 2.3.1 Sequential Assignments for Proteins with Relative Molecular Mass below 15 kDa

The standard notation used for distances in proteins is that the distance between the hydrogen atoms $A$ and $B$ located in the amino acid residues in the sequence positions $i$ and $j$, respectively, is denoted by $d_{AB}(i,j)$. This notation can be applied to all hydrogen atoms, but in practice the distances between different backbone hydrogen atoms and between backbone hydrogens and $\beta$CH$_2$ groups are of particular interest. The standard approach for the sequential assignments of a small ($M_t < 15$ kDa) protein is to carry out the following four steps:

1. **Assign Backbone Residues**
   - Assign $N$-terminal and $C$-terminal residues.
   - Identify $\alpha$-helices and $\beta$-sheets.
   - Use 3D experiments to assign side-chains.

2. **Complete Sequential Assignments**
   - Use 3D and 4D experiments to assign the remaining residues.
   - Cross-peak analysis to confirm assignments.

3. **Assign Secondary Structure**
   - Use distances and torsion angles to assign secondary structure elements.
   - Cross-peak analysis to confirm assignments.

4. **Assign Tertiary Structure**
   - Use long-range NOEs to assign tertiary structure.
   - Cross-peak analysis to confirm assignments.
1. The spin systems of nonlabile protons in individual amino acids are identified for the native protein in D$_2$O by DQFCOSY and TOCSY experiments.

2. From studies in H$_2$O, the identity of amino acid spin systems of the individual residues are completed through identification of the J connectivities with the labile protons.

3. Sequentially neighboring amino acid $^1$H spin systems are identified from observation of the sequential NOE connectivities $d_{NN}$ or $d_{NN}$, or possibly $d_{NN}$.

4. The aim of steps 1–3 is to identify groups of $^1$H-NMR lines corresponding to peptide segments that are sufficiently long to be unique in the primary sequence, or a single residue which is unique. Sequential assignments are then obtained by matching the peptide segments thus identified by NMR with the corresponding segments in the independently determined (not by NMR) amino acid sequence.

For unique residues, the sequential assignment follows directly from the identification of the spin system. For the resonances of unique dipeptide segments, sequential assignments result if a sequential connectivity between the $^1$H spin systems of the two residues can be established. The unique residues and dipeptide segments can then be used as reference locations in the primary structure, so that further sequential identification steps directly provide the sequential assignments for the adjacent residues. The characteristic chemical shifts for random extended chain structures (sometimes inappropriately called random coil) are available.$^{(8)}$ Also the amino acid residues display characteristic cross-peak fine structures in their DQFCOSY spectra. Using this type of information, generally all but the side chains of Lys and Arg beyond the $\beta$CH$_2$ can be readily identified for proteins with $M_r \leq 15000$. Other techniques (e.g. TOCSY) are needed for the complete assignment of all the resonances for Lys and Arg.

The NOEs characteristic of short distances can be identified by comparing NOESY and COSY spectra. Common NOEs correspond to the sequential distances for the i to the $i+1$ residues. The importance of observing the NH signals in H$_2$O is clear. Finally, comparison of the $\alpha$ helix and $\beta$ sheet distances shows that a regular secondary structure can be spotted and categorized by its NOE pattern. $\alpha$-Helices have particularly short sequential $d_{NN}$ values, and $\beta$ sheets have short $d_{NN}$ values. Even more characteristic are the short $d_{NN}(i, i+3)$ and $d_{NN}(i, i+3)$ distances found in helices, and the short interstrand $d_{NN}(i, j)$, $d_{NN}(i, j)$ and $d_{NN}(i, j)$ distances found in $\beta$ sheets. Indeed, even without any sequential assignments, the presence of $d_{NN}$ NOEs can be used as a crude diagnosis for antiparallel $\beta$ sheets.

2.3.2 Sequential Assignments for Proteins with Relative Molecular Mass in the Range 15–50 kDa

For larger proteins the problem of overlapping resonances and increased linewidths can become severe, and the solution is to turn to isotopic labeling and 3D heteronuclear NMR. This is because the heteronuclear couplings, $^{1}J_{CH}$ (125–160 Hz) and $^{1}J_{NH}$ (≈92 Hz), are much larger than $^{1}J_{HH}$, and frequently as much as 50–90% of the magnetization can be transferred from protons to their directly coupled heteronuclei.$^{(63)}$ Consequently, such heteronuclear shift correlation experiments are highly sensitive. The strategy for making 3D heteronuclear NMR assignments relies exclusively on homonuclear and heteronuclear J coupling, which avoids the use of NOE connectivities, and makes use of several different experiments illustrated in Figure 5. The strategy was introduced originally by Markley et al.$^{(64,65)}$ The advantage of avoiding NOE-based strategies for the assignment of larger protein spectra is that it is largely independent of protein conformation, and relies only on one-bond coupling. However, each sequential connectivity depends upon a single correlation. Degeneracy of carbon and nitrogen resonances can be more hampering than degeneracy of proton resonances in the case of the NOE-based assignments, where observation of more than one of the $d_{NN}$, $d_{NN}$ and $d_{NN}$ connectivities can resolve ambiguities. Therefore, these heteronuclear strategies can also be combined with homonuclear NOESY experiments, although the presence of isotopic labeling, for example with $^{13}$C, can exacerbate the linewidth problem for large proteins because the $^{1}$H–$^{13}$C dipolar interaction causes additional proton line broadening.

Typical values for the relevant coupling constants are indicated in Figure 5. Equally important are the magnitudes of the $T_2$ relaxation times, which determine the linewidth and depend approximately linearly on the rotational correlation time, and on the degree of internal mobility and local conformation. Generally, for residues that do not have a high degree of internal mobility in a globular protein of $M_r \approx 20$ kDa at 35°C, the linewidths are about 12 Hz for the NH proton, for $^{15}$NH nitrogen ≈7 Hz ($^1$H coupled) and ≈4 Hz ($^1$H decoupled), ≈15 Hz for $^{13}$C, and ≈25 Hz for a $^{13}$C-attached $^1$H$^*$. The linewidth of the carbonyl is dominated by chemical shift anisotropy and therefore is proportional to the square of $B_0$, and ≈6 Hz at 11.7 T. Comparison of these values with those shown in Figure 5 indicate that for a 20 kDa protein most one-bond J couplings are significantly larger than the linewidths, which means that magnetization can be transferred efficiently from one spin to its directly attached coupling partner. Use of a combination of these experiments permits the complete sequential assignments for proteins up to a maximum
for universal labeling with $^{15}\text{N}$, as $^{15}\text{NH}_4\text{Cl}$ is relatively cheap.

Deuterium labeling can be used to simplify $^1\text{H}$-NMR spectra of proteins.$^{68,69}$ The modern approach has focused on reducing the $^1\text{H}^\to^1\text{H}$ dipolar interaction through fractional deuterium labeling.$^{70\text{–}72}$ There are a number of advantages to the use of deuterium for NMR studies of larger proteins. Random deuteration helps to reduce spin diffusion, and incorporation of stereospecifically deuterated amino acids helps to resolve degenerate proton resonances and enable quantitative NOE analysis. Chiral deuteration can aid in stereospecific assignments, but is rarely employed because it is experimentally difficult.

2.3.3 Methods for Extending the Molecular Weight Limit

There are a number of approaches for extending the molecular weight limit that NMR imposes on the study of biomolecules. At the root of the problem is the fact that larger molecular weight particles tumble more slowly, generally leading to longer correlation times ($\tau_c$), which in turn leads to broader lines. Therefore approaches that narrow these broad lines are what is required. One rather obvious approach is to stop the molecular tumbling by going to the solid state, and then to employ the methods of solid-state NMR such as cross-polarization/magic-angle spinning (CP/MAS) to narrow the lines. These techniques throw away important information, such as the dipolar coupling, so techniques to reintroduce these couplings are necessary (section 4) for solid-state NMR to be useful in structural biology. In solution, a number of approaches have been introduced which can be used separately or in concert. Use of deuteration labeling, as discussed in the previous section, helps to reduce linewidths substantially. Also Hahn spin–echo sequences can be used to edit with respect to broad lines in the presence of narrow lines. Recently a new approach called transverse relaxation optimized spectroscopy (TROSY) has been introduced$^{73}$ which relies on the cancellation of two competing effects at high magnetic field strength. These effects are the dipolar relaxation and chemical shift anisotropic relaxation. Some TROSY variants on the complete set of standard 3D protein NMR pulse sequences have been introduced.$^{74,75}$ It has been suggested$^{73}$ that these approaches will be applicable to proteins up to 500 kDa. In practice the benefits depend on the system under study, and in some situations TROSY versions of 3D experiments are preferable for large proteins even at low field strengths (500–600 MHz $^1\text{H}$), and in some cases the significant loss of sensitivity with TROSY is too high a price to pay.
3 BIOMOLECULAR STRUCTURE DETERMINATION

The application of NMR spectroscopy both in solution and in the solid state can generate a variety of distance and angle restraints that can be used in computing the 3D structure of a biomolecule. These restraints can only be interpreted once the spectral assignments have been made, and may be obtained in a number of ways. The accuracy of distance and angle measurements depends largely on the technique, with those methods that yield the lowest number of restraints tending to give more accurate data, although in the case of solid-state NMR data this usually defines the local rather than the global structure. However, accuracy is not always required in order to determine a structure with high precision. Protein structures can be obtained with high precision with relatively poorly defined distance restraints, such as those obtained from NOESY experiments. However, the same does not hold for DNA, for which accurate distances are required. Furthermore, the use of NOEs is generally confined to those molecules whose molecular weight is below 20 000. In the same spectra, medium NOEs appear as weak cross-peaks. The weak NOEs appear only at longer mixing times (e.g. $\tau_m = 200$ ms for a protein whose $M_r$ is below 20 000). In the same spectra, medium NOEs appear as weak cross-peaks. The weak NOEs appear only at longer mixing times (e.g. $\tau_m = 200$ ms for a protein whose $M_r$ is below 20 000) and may be due to indirect effects. The lower bound is kept the same for each category because local motion could severely attenuate the NOE, even for short distances. These distance bounds or restraints are used as input into computer algorithms for the calculation of the 3D structure (sections 3.3 and 3.4). Even though only ranges of distances for a given pair of atoms can be found, these restrict drastically the number of possible structures, and refinement protocols (section 3.6) ensure that a low-energy structure can be determined.

3.2 Use of $J$ Couplings to Obtain Torsion Angles

Judicious use of the Karplus relation ($J = A + B \cos \theta + C \cos^2 \theta$) yields information on the dihedral angles.$^{(76,77)}$ The constants in the Karplus relationship have been determined empirically. In proteins, the couplings of interest are the three-bond couplings; in particular, $J_{\text{HN},\text{N}}$ is related to the angle $\phi$, and $J_{\text{HN},\text{H}}$ and $J_{\text{N},\text{H}}$ are related to $\chi_1$. These relationships have been calibrated on known structures$^{(78,79)}$ and are given in Equation (12) (in Hertz):

$$
\begin{align*}
J_{\text{HN},\text{N}}(\phi) &= 6.4 \cos^2(\phi - 60^\circ) \\
& \quad - 1.4 \cos(\phi - 60^\circ) + 1.9 \\
J_{\text{HN},\text{H}}(\chi_1) &= 9.5 \cos^2(\chi_1 - 120^\circ) \\
& \quad - 1.6 \cos(\chi_1 - 120^\circ) + 1.8 \\
J_{\text{N},\text{H}}(\chi_2) &= 9.5 \cos^2(\chi_1 - 1.6 \cos \chi_1 + 1.8) \\
& \quad - 4.5 \cos^2(\chi_1 + 120^\circ) + 0.1 \\
J_{\text{N},\text{H}}(\chi_3) &= -4.5 \cos^2(\chi_1 - 120^\circ) \\
& \quad + 1.2 \cos(\chi_1 + 120^\circ) + 0.1
\end{align*}
$$

Using these equations, the dihedral angles $\phi$ and $\chi_1$ may be calculated from both homonuclear and heteronuclear couplings.$^{(80)}$ There are corresponding important dihedral...
angles in other types of biomolecules, such as in DNA and carbohydrates.

Accurate measurement of $J$ couplings in an overlapping one-dimensional spectrum of a biomolecule can be very difficult. Two-bond and three-bond coupling constants may be extracted with care from the antiphase multiplet structure of the cross-peaks in phase-sensitive COSY or DQFCOSY. A better approach is to use one of a number of modified COSY experiments which simplify the cross-peak multiplet structure, such as ECOSY\(^{(83)}\) (exclusive correlation spectroscopy), or PECOSY\(^{(82)}\) (primitive exclusive correlation spectroscopy). The disadvantage of the ECOSY experiment is that it has very low sensitivity. The PECOSY experiment is at least four times more sensitive than the ECOSY experiment.

For larger biomolecules, measurement of $J$ couplings from the PECOSY spectrum is difficult because of extensive resonance overlap. In these cases, an estimate of the values for $J$ couplings may be obtained with $^{15}$N-labeled material, from the cross-peaks in a 3D $^1$H–$^{15}$N TOCSY/HMQC spectrum. The extent of magnetization transfer during the Hartmann–Hahn spin-lock depends on the magnitude of the scalar $J$ coupling.

The measured coupling constant represents the time average (on the 100-ms timescale) of the actual $J$ coupling. Thus the interpretation of a measured $J$ coupling can be hampered by uncertainty as to whether it represents a $J$ value that corresponds to a single dihedral angle, or whether it represents a rapid averaging of $J$ values from quite different dihedral angles. When a biological molecule does not exist as a single conformation, but as an equilibrium of rapidly interconverting conformers, the NOE and $J$ contain time-averaged distance and angle information. Both averaging processes are strongly nonlinear in their dependence on geometry, and the presence of multiple conformations can lead to NOEs and $J$ couplings that cannot simultaneously be consistent with a single conformation.

The stereospecific assignment of resonances in a biomolecule, for example the $\beta$-methylene protons or methyl resonances of leucine or valine, can be extremely important in defining local conformations. Early NMR structures were obtained by treating NOEs involving chiral protons with indistinguishable chemical shifts ($<0.01$ ppm) as a single distance to the geometric center between the two methylene protons, with a 1 Å correction added to the upper bound of the measured distance to correct for the difference in position of the so-called pseudo-atom relative to the true proton. Similarly the distance to the geometric center of a methyl group was used with a corresponding increase of 2.4 Å to the upper bound for the measured distance. Instead of using pseudo-atoms, a more rigorous approach is to match the experimental NOEs and $J$ coupling constants with those calculated for conformations present in a database. Both possible stereospecific assignments are considered, and if the database contains only conformations consistent with one of the two possibilities, then the correct assignment, together with the allowed ranges for $\phi$, $\psi$, and $\chi_1$, can be determined. In practice only about 50% of the possible stereospecific assignments can be made in an unambiguous manner.

The $J_{HN}$ can be used in crude calculations to provide $\phi$ backbone torsion-angle restraints, which for proteins can be classified into two ranges: $J_{HN} < 6$ Hz corresponding to $-35^\circ < \phi < -85^\circ$; and $J_{HN} > 8$ Hz corresponding to $-80^\circ < \phi < -175^\circ$. Refinement of these numbers using the methods already outlined, including more accurate $\phi$, $\psi$, and $\chi_1$ torsion angles and stereospecific assignments, can almost double the number of experimental restraints that are used as input to distance geometry and related algorithms. As a general rule of thumb, helices exhibit $J_{HN} < 6$ Hz, $\beta$-sheets exhibit $J_{HN} > 8$ Hz, and random extended chains exhibit $J_{HN} = 6–8$ Hz. Note, however, that deviations from this rule occur when proline is present.

### 3.3 Distance Geometry
